

22.12: BIOLOGICAL ACYLATION REACTIONS

GLUTAMINE SYNTHETASE

The carboxylate functional group is a very unreactive substrate for an enzyme-catalyzed acyl substitution reactions. How, then, does a living system accomplish an 'uphill' reaction such as the one shown below, where glutamate (a carboxylate) is converted to glutamine (an amide)?

It turns out that this conversion is not carried out directly. Rather, the first conversion is from a carboxylate (the *least* reactive acyl transfer substrate) to an acyl phosphate (the *most* reactive acyl transfer substrate). This transformation requires a reaction that we are familiar with from chapter 10: phosphorylation of a carboxylate oxygen with ATP as the phosphate donor.

Note that this is just one of the many ways that ATP is used as an energy storage unit: in order to make a high energy acyl phosphate molecule from a low energy carboxylate, the cell must 'spend' the energy of one ATP molecule.

The acyl phosphate version of glutamate is now ready to be converted directly to an amide (glutamine) *via* a nucleophilic acyl substitution reaction, as an ammonia molecule attacks the carbonyl and the phosphate is expelled.

Overall, this reaction can be written as:

ASPARAGINE SYNTHETASE

Another common form of activated carboxylate group is an acyl adenosine phosphate. Consider another amino acid reaction, the conversion of aspartate to asparagine. In the first step, the carboxylate group of aspartate must be activated:

Once again, ATP provides the energy for driving the uphill reaction. This time, however, the activated carboxylate takes the form of an acyl adenosine (mono)phosphate. All that has happened is that the carboxylate oxygen has attacked the α -phosphate of ATP rather than the γ -phosphate.

The reactive acyl-AMP version of aspartate is now ready to be converted to an amide (asparagine) via nucleophilic attack by ammonia. In the case of glutamine synthase, the source of ammonia was free ammonium ion in solution. In the case of asparagine synthase, the NH_3 is derived from the hydrolysis of glutamine (this is simply another acyl substitution reaction):

The hydrolysis reaction is happening in the same enzyme active site – as the NH_3 is expelled in the hydrolysis of glutamine, it immediately turns around and acts as the nucleophile in the conversion of aspartyl-AMP to asparagine:

Keep in mind that the same enzyme is also binding ATP and using it to activate aspartate – this is a busy construction zone!

Overall, this reaction can be written in condensed form as:

GLYCINAMIDE RIBONUCLEOTIDE SYNTHETASE

The diagram illustrates the initial steps of purine biosynthesis. It begins with the conversion of glycine to 5-phosphoribosylamine (5-PRAM) via a reaction involving ATP and ADP. The glycine molecule is shown with a green amino group and a blue carboxylate group. The 5-PRAM molecule has a green amino group and a blue phosphate group. The reaction is catalyzed by the enzyme GAR transformylase. The next step shows the conversion of 5-PRAM to glycinamide ribonucleotide (GAR) via a reaction involving ATP and ADP. The GAR molecule has a green amino group and a blue phosphate group. The reaction is catalyzed by the enzyme GAR synthetase. The final step shows the conversion of GAR to AMP and GMP via a reaction involving many steps. The AMP and GMP molecules are shown with a green amino group and a blue phosphate group. The reaction is catalyzed by the enzyme GAR synthetase.

glycine

ATP

ADP

5-phosphoribosylamine

glycinamide ribonucleotide

many steps

AMP

GMP
