In particular, note that with our new notation,  $N_t = N[0,t]$  for  $t \ge 0$  and  $N(s,t] = N_t - N_s$  for  $s \le t$ . Thus, the random counting measure is completely determined by the counting process. The counting process is the "cumulative measure function" for the counting measure, analogous the cumulative distribution function of a probability measure.

For  $t \ge 0$  and  $n \in \mathbb{N}$ , 1.  $T_n \le t$  if and only if  $N_t \ge n$ 2.  $N_t = n$  if and only if  $T_n \le t < T_{n+1}$ 

#### Proof

Note that the event in part (a) means that at there are at least n arrivals in [0, t]. The event in part (b) means that there are exactly n arrivals in [0, t].

Of course, the complements of the events in (a) are also equivalent, so  $T_n > t$  if and only if  $N_t < n$ . On the other hand, neither of the events  $N_t \le n$  and  $T_n \ge t$  implies the other. For example, we couse easily have  $N_t = n$  and  $T_n < t < T_{n+1}$ . Taking complements, neither of the events  $N_t > n$  and  $T_n < t$  implies the other. The last result also shows that the arrival time process T and the counting process N are inverses of each other in a sense.

```
The following events have probability 1:

1. N_t < \infty for all t \in [0, \infty)
```

```
1. N_t < \infty \, 	ext{ for all } t \in [0,\infty)
2. N_t 	o \infty \, 	ext{ as } t 	o \infty
Proof
```

The event in part (a) occurs if and only if  $T_n \to \infty$  as  $n \to \infty$ , which occurs with probability 1 by the result above. The event in part (b) occurs if and only if  $T_n < \infty$  for all  $n \in \mathbb{N}$  which also occurs with probability 1.

All of the results so far in this subsection show that the arrival time process T and the counting process N are inverses of one another in a sense. The important equivalences above can be used to obtain the probability distribution of the counting variables in terms of the interarrival distribution function F.

$$egin{array}{lll} ext{For} \ t\geq 0 \ ext{and} \ n\in\mathbb{N}, \ 1. \ \mathbb{P}(N_t\geq n)=F_n(t) \ 2. \ \mathbb{P}(N_t=n)=F_n(t)-F_{n+1}(t) \end{array}$$

The next result is little more than a restatement of the result above relating the counting process and the arrival time process. However, you may need to review the section on filtrations and stopping times to understand the result

For  $t \in [0, \infty)$ ,  $N_t + 1$  is a stopping time for the sequence of interarrival times X

Proof

Note that  $N_t + 1$  takes values in  $\mathbb{N}_+$ , so we need to show that the event  $\{N_t + 1 = n\}$  is measurable with respect to  $\mathscr{P}_n = \sigma\{X_1, X_2, \ldots, X_n\}$  for  $n \in \mathbb{N}_+$ . But from the result above,  $N_t + 1 = n$  if and only if  $N_t = n - 1$  if and only if  $T_{n-1} \leq t < T_n$ . The last event is clearly measurable with respect to  $\mathscr{P}_n$ .

#### The Renewal Function

The function M that gives the expected number of arrivals up to time t is known as the *renewal function*:

$$M(t) = \mathbb{E}(N_t), \quad t \in [0, \infty)$$
 (15.1.8)

The renewal function turns out to be of fundamental importance in the study of renewal processes. Indeed, the renewal function essentially characterizes the renewal process. It will take awhile to fully understand this, but the following theorem is a first step:

The renewal function is given in terms of the interarrival distribution function by

$$M(t) = \sum_{n=1}^{\infty} F_n(t), \quad 0 \le t < \infty$$
 (15.1.9)

Proof

Recall that  $N_t = \sum_{n=1}^{\infty} \mathbf{1}(T_n \leq t)$ . Taking expected values gives the result. Note that the interchange of sum and expected value is valid because the terms are nonnegative.

Note that we have not yet shown that  $M(t) < \infty$  for  $t \ge 0$ , and note also that this does not follow from the previous theorem. However, we will establish this finiteness condition in the subsection on moment generating functions below. If M is differentiable, the derivative m = M' is known as the *renewal density*, so that m(t) gives the expected rate of arrivals per unit time at  $t \in [0, \infty)$ .

More generally, if *A* is a (measurable) subset of  $[0, \infty)$ , let  $M(A) = \mathbb{E}[N(A)]$ , the expected number of arrivals in *A*.

*M* is a positive measure on  $[0, \infty)$ . This measure is known as the *renewal measure*.

#### Proof

*N* is a measure on  $[0, \infty)$  (albeit a random one). So if  $(A_1, A_2, ...)$  is a sequence of disjoint, measurable subsets of  $[0, \infty)$  then

$$N\left(\bigcup_{i=1}^{\infty} A_i\right) = \sum_{i=1}^{\infty} N(A_i)$$
(15.1.10)

Taking expected values gives

$$m\left(\bigcup_{i=1}^{\infty} A_i\right) = \sum_{i=1}^{\infty} m(A_i)$$
(15.1.11)

Again, the interchange of sum and expected value is justified since the terms are nonnegative.

The renewal measure is also given by

$$M(A) = \sum_{n=1}^{\infty} \mathbb{P}(T_n \in A), \quad A \subset [0, \infty)$$
 (15.1.12)

Proof

Recall that  $N(A) = \sum_{n=1}^{\infty} \mathbf{1}(T_n \in A)$ . Taking expected values gives the result. Again, the interchange of expected value and infinite series is justified since the terms are nonnegative.

If  $s \ t \in [0,\infty)$  with  $s \le t$  then M(t) - M(s) = m(s,t], the expected number of arrivals in (s,t].

The last theorem implies that the renewal function actually determines the entire renewal measure. The renewal function is the "cumulative measure function", analogous to the cumulative distribution function of a probability measure. Thus, every renewal process naturally leads to two measures on  $[0, \infty)$ , the random counting measure corresponding to the arrival times, and the measure associated with the expected number of arrivals.

The Age Processes

For  $t \in [0,\infty)$ ,  $T_{N_t} \leq t < T_{N_t+1}$  . That is, t is in the random renewal interval  $[T_{N_t}, T_{N_t+1})$ .

Consider the reliability setting in which whenever a device fails, it is immediately replaced by a new device of the same type. Then the sequence of interarrival times X is the sequence of lifetimes, while  $T_n$  is the time that the *n*th device is placed in service. There are several other natural random processes that can be defined.

The random variable

$$C_t = t - T_{N_t}, \quad t \in [0, \infty)$$
 (15.1.13)

is called the *current life* at time *t*. This variable takes values in the interval [0, t] and is the age of the device that is in service at time *t*. The random process  $C = (C_t : t \ge 0)$  is the *current life process*.

The random variable

$$R_t = T_{N_t+1} - t, \quad t \in [0,\infty)$$
 (15.1.14)

is called the *remaining life* at time *t*. This variable takes values in the interval  $(0, \infty)$  and is the time remaining until the device that is in service at time *t* fails. The random process  $\mathbf{R} = (R_t : t \ge 0)$  is the *remaining life process*.

Figure 15.1.3: The current and remaining life at time t

The random variable

$$L_t = C_t + R_t = T_{N_t+1} - T_{N_t} = X_{N_t+1}, \quad t \in [0, \infty)$$
(15.1.15)

is called the *total life* at time *t*. This variable takes values in  $[0, \infty)$  and gives the total life of the device that is in service at time *t*. The random process  $L = (L_t : t \ge 0)$  is the *total life process*.

Tail events of the current and remaining life can be written in terms of each other and in terms of the counting variables.

Suppose that  $t \in [0, \infty)$ ,  $x \in [0, t]$ , and  $y \in [0, \infty)$ . Then

1. 
$$\{R_t > y\} = \{N_{t+y} - N_t = 0\}$$
  
2.  $\{C_t \ge x\} = \{R_{t-x} > x\} = \{N_t - N_{t-x} = 0\}$   
3.  $\{C_t \ge x, R_t > y\} = \{R_{t-x} > x + y\} = \{N_{t+y} - N_{t-x} = 0\}$   
Proof

 $\xrightarrow{C_t} \begin{array}{c} R_t \\ \hline \\ 0 \end{array} \xrightarrow{T_{N_t}} \begin{array}{c} t-x & t \end{array} \xrightarrow{t+y} \begin{array}{c} T_{N_t+1} \end{array} \xrightarrow{T_{N_t+1}} \end{array}$ 

Figure 15.1.4: The events of interest for the current and remaining life

Of course, the various equivalent events in the last result must have the same probability. In particular, it follows that if we know the distribution of  $R_t$  for all t then we also know the distribution of  $C_t$  for all t, and in fact we know the joint distribution of  $(R_t, C_t)$  for all t and hence also the distribution of  $L_t$  for all t.

For fixed  $t \in (0, \infty)$  the total life at t (the lifetime of the device in service at time t) is stochastically larger than a generic lifetime. This result, a bit surprising at first, is known as the *inspection paradox*. Let X denote fixed interarrival time.

$$\mathbb{P}(L_t>x)\geq \mathbb{P}(X>x) ext{ for } x\geq 0.$$

Proof

Recall that  $L_t = X_{N_t+1}$ . The proof is by conditioning on  $N_t$ . An important tool is the fact that if A and B are nested events in a probability space (one a subset of the other), then the events are positively correlated, so that  $\mathbb{P}(A \mid B) \ge \mathbb{P}(A)$ . Recall that F is the common CDF of the interarrival times. First

$$\mathbb{P}(X_{N_t+1} > x \mid N_t = 0) = \mathbb{P}(X_1 > x \mid X_1 > t) \ge \mathbb{P}(X_1 > x) = 1 - F(x)$$
(15.1.16)

Next, for  $n \in \mathbb{N}_+$  ,

$$\mathbb{P}(X_{N_t+1} > x \mid N_t = n) = \mathbb{P}(X_{n+1} > x \mid T_n \le t < T_{n+1}) = \mathbb{P}(X_{n+1} > x \mid T_n \le t < T_n + X_{n+1})$$
(15.1.17)

We condition this additionally on  $T_n$ , the time of the *n*th arrival. For  $s \le t$ , and since  $X_{n+1}$  is independent of  $T_n$ , we have

$$\mathbb{P}(X_{n+1} > x \mid T_n = s, \ X_{n+1} > t - s) = \mathbb{P}(X_{n+1} > x \mid X_{n+1} > t - s) \ge \mathbb{P}(X_{n+1} > x) = 1 - F(x) \quad (15.1.18)$$

It follows that  $\mathbb{P}\left(X_{N_t+1} > x \mid N_t = n
ight) \geq 1 - F(x) \quad ext{for every } n \in \mathbb{N}, ext{ and hence}$ 

$$\mathbb{P}\left(X_{N_t+1} > x\right) = \sum_{n=0}^{\infty} \mathbb{P}\left(X_{N_t+1} > x \mid N_t = n\right) \mathbb{P}(N_t = n) \ge \sum_{n=0}^{\infty} \left[1 - F(x)\right] \mathbb{P}(N_n = n) = 1 - F(x) \quad (15.1.19)$$

#### **Basic Comparison**

The basic comparison in the following result is often useful, particularly for obtaining various bounds. The idea is very simple: if the interarrival times are shortened, the arrivals occur more frequently.

Suppose now that we have two interarrival sequences,  $X = (X_1, X_2, ...)$  and  $Y = (Y_1, Y_2, ...)$  defined on the same probability space, with  $Y_i \leq X_i$  (with probability 1) for each *i*. Then for  $n \in \mathbb{N}$  and  $t \in [0, \infty)$ ,

 $egin{aligned} 1. \ T_{Y,n} &\leq T_{X,n} \ 2. \ N_{Y,t} &\geq N_{X,t} \ 3. \ m_Y(t) &\geq m_X(t) \end{aligned}$ 

#### Examples and Special Cases

#### Bernoulli Trials

Suppose that  $X = (X_1, X_2, ...)$  is a sequence of Bernoulli trials with success parameter  $p \in (0, 1)$ . Recall that X is a sequence of independent, identically distributed indicator variables with  $\mathbb{P}(X = 1) = p$ .

Recall the random processes derived from X:

1.  $\mathbf{Y} = (Y_0, Y_1, ...)$  where  $Y_n$  the number of success in the first n trials. The sequence  $\mathbf{Y}$  is the partial sum process associated with  $\mathbf{X}$ . The variable  $Y_n$  has the binomial distribution with parameters n and p.

- 2.  $U = (U_1, U_2, ...)$  where  $U_n$  the number of trials needed to go from success number n 1 to success number n. These are independent variables, each having the geometric distribution on  $\mathbb{N}_+$  with parameter p.
- 3.  $V = (V_0, V_1, ...)$  where  $V_n$  is the trial number of success n. The sequence V is the partial sum process associated with U. The variable  $V_n$  has the negative binomial distribution with parameters n and p.

It is natural to view the successes as arrivals in a discrete-time renewal process.

Consider the renewal process with interarrival sequence U. Then

- 1. The basic assumptions are satisfied and that the mean interarrival time is  $\mu = 1/p$ .
- 2. *V* is the sequence of arrival times.
- 3.  $\boldsymbol{Y}$  is the counting process (restricted to  $\mathbb{N}$ ).
- 4. The renewal function is m(n) = np for  $n \in \mathbb{N}$ .

It follows that the renewal measure is proportional to counting measure on  $\mathbb{N}_+$ .

Run the binomial timeline experiment 1000 times for various values of the parameters n and p. Compare the empirical distribution of the counting variable to the true distribution.

Run the negative binomial experiment 1000 times for various values of the parameters k and p. Comare the empirical distribution of the arrival time to the true distribution.

Consider again the renewal process with interarrival sequence U. For  $n \in \mathbb{N}$ ,

- 1. The current life and remaining life at time n are independent.
- 2. The remaining life at time *n* has the same distribution as an interarrival time *U*, namely the geometric distribution on  $\mathbb{N}_+$  with parameter *p*.
- 3. The current life at time n has a truncated geometric distribution with parameters n and p:

$$\mathbb{P}(C_n = k) = \begin{cases} p(1-p)^k, & k \in \{0, 1, \dots, n-1\} \\ (1-p)^n, & k = n \end{cases}$$
(15.1.20)

Proof

These results follow from age process events above.

This renewal process starts over, independently of the past, not only at the arrival times, but at fixed times  $n \in \mathbb{N}$  as well. The Bernoulli trials process (with the successes as arrivals) is the only discrete-time renewal process with this property, which is a consequence of the memoryless property of the geometric interarrival distribution.

We can also use the indicator variables as the interarrival times. This may seem strange at first, but actually turns out to be useful.

Consider the renewal process with interarrival sequence X.

- 1. The basic assumptions are satisfied and that the mean interarrival time is  $\mu = p$ .
- 2. *Y* is the sequence of arrival times.
- 3. The number of arrivals at time 0 is  $U_1 1$  and the number of arrivals at time  $i \in \mathbb{N}_+$  is  $U_{i+1}$ .
- 4. The number of arrivals in the interval [0, n] is  $V_{n+1} 1$  for  $n \in \mathbb{N}$ . This gives the counting process.
- 5. The renewal function is  $m(n) = \frac{n+1}{p} 1$  for  $n \in \mathbb{N}$ .

The age processes are not very interesting for this renewal process.

For  $n \in \mathbb{N}$  (with probability 1),

1.  $C_n = 0$ 

2.  $R_n = 1$ 

## The Moment Generating Function of the Counting Variables

As an application of the last renewal process, we can show that the moment generating function of the counting variable  $N_t$  in an arbitrary renewal process is finite in an interval about 0 for every  $t \in [0, \infty)$ . This implies that  $N_t$  has finite moments of all orders and in particular that  $m(t) < \infty$  for every  $t \in [0, \infty)$ .

Suppose that  $\mathbf{X} = (X_1, X_2, ...)$  is the interarrival sequence for a renewal process. By the basic assumptions, there exists a > 0 such that  $p = \mathbb{P}(X \ge a) > 0$ . We now consider the renewal process with interarrival sequence  $\mathbf{X}_a = (X_{a,1}, X_{a,2}, ...)$ , where  $X_{a,i} = a \mathbf{1}(X_i \ge a)$  for  $i \in \mathbb{N}_+$ . The renewal process with interarrival sequence  $\mathbf{X}_a$  is just like the renewal process with Bernoulli interarrivals, except that the arrival times occur at the points in the sequence (0, a, 2a, ...), instead of (0, 1, 2, ...).

For each  $t \in [0, \infty)$ ,  $N_t$  has finite moment generating function in an interval about 0, and hence  $N_t$  has moments of all orders at 0.

#### Proof

Note first that  $X_{a,i} \leq X_i$  for each  $i \in \mathbb{N}_+$ . Recall the moment generating function  $\Gamma$  of the geometric distribution with parameter p is

$$\Gamma(s) = rac{e^s p}{1 - (1 - p)e^s}, \quad s < -\ln(1 - p)$$
(15.1.21)

But as with the process with Bernoulli interarrival times,  $N_{a,t}$  can be written as  $a(V_{n+1}-1)$  where  $n = \lfloor a/t \rfloor$  and where  $V_{n+1}$  is a sum of n+1 IID geometric variables, each with parameter p. We don't really care about the explicit form of the MGF of  $N_{a,t}$ , but it is clearly finite in an interval of the from  $(-\infty, \epsilon)$  where  $\epsilon > 0$ . But  $N_t \leq N_{t,a}$ , so its MGF is also finite on this interval.

## The Poisson Process

The *Poisson process*, named after Simeon Poisson, is the most important of all renewal processes. The Poisson process is so important that it is treated in a separate chapter in this project. Please review the essential properties of this process:

Properties of the Poisson process with rate  $r \in (0,\infty)$ .

- 1. The interarrival times have an exponential distribution with rate parameter r. Thus, the basic assumptions above are satisfied and the mean interarrival time is  $\mu = 1/r$ .
- 2. The exponential distribution is the only distribution with the memoryless property on  $[0, \infty)$ .
- 3. The time of the *n*th arrival  $T_n$  has the gamma distribution with shape parameter n and rate parameter r.
- 4. The counting process  $N = (N_t : t \ge 0)$  has stationary, independent increments and  $N_t$  has the Poisson distribution with parameter rt for  $t \in [0, \infty)$ .
- 5. In particular, the renewal function is m(t) = rt for  $t \in [0, \infty)$ . Hence, the renewal measure is a multiple of the standard length measure (Lebesgue measure) on  $[0, \infty)$ .

Consider again the Poisson process with rate parameter r. For  $t \in [0, \infty)$ ,

- 1. The current life and remaining life at time t are independent.
- 2. The remaining life at time t has the same distribution as an interarrival time X, namely the exponential distribution with rate parameter r.
- 3. The current life at time *t* has a truncated exponential distribution with parameters *t* and *r*:

$$\mathbb{P}(C_t \ge s) = \begin{cases} e^{-rs}, & 0 \le s \le t \\ 0, & s > t \end{cases}$$
(15.1.22)

Proof

These results follow from age process events given above.

The Poisson process starts over, independently of the past, not only at the arrival times, but at fixed times  $t \in [0, \infty)$  as well. The Poisson process is the only renewal process with this property, which is a consequence of the memoryless property of the exponential interarrival distribution.

# 

Run the Poisson experiment 1000 times for various values of the parameters t and r. Compare the empirical distribution of the counting variable to the true distribution.

Run the gamma experiment 1000 times for various values of the parameters n and r. Compare the empirical distribution of the arrival time to the true distribution.

## Simulation Exercises

Open the renewal experiment and set t = 10. For each of the following interarrival distributions, run the simulation 1000 times and note the shape and location of the empirical distribution of the counting variable. Note also the mean of the interarrival distribution in each case.

- 1. The continuous uniform distribution on the interval [0, 1] (the standard uniform distribution).
- 2. the discrete uniform distribution starting at a = 0, with step size h = 0.1, and with n = 10 points.
- 3. The gamma distribution with shape parameter k = 2 and scale parameter b = 1.
- 4. The beta distribution with left shape parameter a = 3 and right shape parameter b = 2.
- 5. The exponential-logarithmic distribution with shape parameter p = 0.1 and scale parameter b = 1.
- 6. The Gompertz distribution with shape paraemter a = 1 and scale parameter b = 1.
- 7. The Wald distribution with mean  $\mu = 1$  and shape parameter  $\lambda = 1$ .
- 8. The Weibull distribution with shape parameter k = 2 and scale parameter b = 1.

# 15.2: Renewal Equations

Many quantities of interest in the study of renewal processes can be described by a special type of integral equation known as a *renewal* equation. Renewal equations almost always arise by conditioning on the time of the first arrival and by using the defining property of a renewal process—the fact that the process restarts at each arrival time, independently of the past. However, before we can study renewal equations, we need to develop some additional concepts and tools involving measures, convolutions, and transforms. Some of the results in the advanced sections on measure theory, general distribution functions, the integral with respect to a measure, properties of the integral, and density functions are needed for this section. You may need to review some of these topics as necessary. As usual, we assume that all functions and sets that are mentioned are measurable with respect to the appropriate  $\sigma$ -algebras. In particular,  $[0, \infty)$  which is our basic temporal space, is given the usual Borel  $\sigma$ -algebra generated by the intervals.

## Measures, Integrals, and Transforms

#### **Distribution Functions and Positive Measures**

Recall that a distribution function on  $[0, \infty)$  is a function  $G : [0, \infty) \to [0, \infty)$  that is increasing and continuous from the right. The distribution function G defines a positive measure on  $[0, \infty)$ , which we will also denote by G, by means of the formula G[0, t] = G(t) for  $t \in [0, \infty)$ .

Figure 15.2.1: G(t) is the cumulative measure at t

Hopefully, our notation will not cause confusion and it will be clear from context whether G refers to the positive measure (a set function) or the distribution function (a point function). More generally, if  $a, b \in [0, \infty)$  and  $a \leq b$  then G(a, b] = G(b) - G(a). Note that the positive measure associated with a distribution function is *locally finite* in the sense that  $G(A) < \infty$  is  $A \subset [0, \infty)$  is bounded. Of course, if A is unbounded, G(A) may well be infinite. The basic structure of a distribution function and its associated positive measure occurred several times in our preliminary discussion of renewal processes:

Distributions associated with a renewal process.

- 1. The distribution function F of the interarrival times defines a probability measure on  $[0,\infty)$
- 2. The counting process N defines a (random) counting measure on  $[0,\infty)$
- 3. the renewal function M defines a (deterministic) positive measure on  $[0,\infty)$

Suppose again that *G* is a distribution function on  $[0, \infty)$ . Recall that the integral associated with the positive measure *G* is also called the *Lebesgue-Stieltjes integral* associated with the distribution function *G* (named for Henri Lebesgue and Thomas Stieltjes). If  $f : [0, \infty) \to \mathbb{R}$  and  $A \subseteq [0, \infty)$  (measurable of course), the integral of *f* over *A* (if it exists) is denoted

$$\int_{A} f(t) \, dG(t) \tag{15.2.1}$$

We use the more conventional  $\int_0^t f(x) dG(x)$  for the integral over [0, t] and  $\int_0^\infty f(x) dG(x)$  for the integral over  $[0, \infty)$ . On the other hand,  $\int_s^t f(x) dG(x)$  means the integral over (s, t] for s < t, and  $\int_s^\infty f(x) dG(x)$  means the integral over  $(s, \infty)$ . Thus, the additivity of the integral over disjoint domains holds, as it must. For example, for  $t \in [0, \infty)$ ,

$$\int_0^\infty f(x) \, dG(x) = \int_0^t f(x) \, dG(x) + \int_t^\infty f(x) \, dG(x) \tag{15.2.2}$$

This notation would be ambiguous without the clarification, but is consistent with how the measure works: G[0, t] = G(t) for  $t \ge 0$ , G(s, t] = G(t) - G(s) for  $0 \le s < t$ , etc. Of course, if *G* is continuous as a *function*, so that *G* is also continuous as a *measure*, then none of this matters—the integral over an interval is the same whether or not endpoints are included. The following definition is a natural complement to the locally finite property of the positive measures that we are considering.

A function  $f : [0, \infty) \to \mathbb{R}$  is *locally bounded* if it is measurable and is bounded on [0, t] for each  $t \in [0, \infty)$ .

The locally bounded functions form a natural class for which our integrals of interest exist.

Suppose that *G* is a distribution function on  $[0, \infty)$  and  $f : [0, \infty) \to \mathbb{R}$  is locally bounded. Then  $g : [0, \infty) \to \mathbb{R}$  defined by  $g(t) = \int_0^t f(s) \, dG(s)$  is also locally bounded.

#### Proof

Suppose that  $|f(s)| \leq C_t$  for  $s \in [0, t]$  and  $t \in [0, \infty)$ . Then

$$\int_{0}^{s} |f(x)| \; dG(x) \leq C_t G(s) \leq C_t G(t), \quad t \in [0,\infty)$$
 (15.2.3)

Hence *f* is integrable on [0, s] and the integral is bounded by  $C_t G(t)$  for  $s \in [0, t]$ .

Note that if *f* and *g* are locally bounded, then so are f + g and *fg*. If *f* is increasing on  $[0, \infty)$  then *f* is locally bounded, so in particular, a distribution function on  $[0, \infty)$  is locally bounded. If *f* is continuous on  $[0, \infty)$  then *f* is locally bounded. Similarly, if *G* and *H* are distribution functions on  $[0, \infty)$  and if  $c \in (0, \infty)$ , then G + H and cG are also distribution functions on  $[0, \infty)$ . Convolution, which we consider next, is another way to construct new distributions on  $[0, \infty)$  from ones that we already have.

#### Convolution

The term *convolution* means different things in different settings. Let's start with the definition we know, the convolution of probability density functions, on our space of interest  $[0, \infty)$ .

Suppose that *X* and *Y* are independent random variables with values in  $[0, \infty)$  and with probability density functions *f* and *g*, respectively. Then *X* + *Y* has probability density function *f* \* *g* given as follows, in the discrete and continuous cases, respectively

$$(f*g)(t) = \sum_{s \in [0,t]} f(t-s)g(s)$$
(15.2.4)

$$(f * g)(t) = \int_0^t f(t-s)g(s) \, ds \tag{15.2.5}$$

In the discrete case, it's understood that t is a possible value of X + Y, and the sum is over the countable collection of  $s \in [0, t]$  with s a value of X and t - s a value of Y. Often in this case, the random variables take values in  $\mathbb{N}$ , in which case the sum is simply over the set  $\{0, 1, \ldots, t\}$  for  $t \in \mathbb{N}$ . The discrete and continuous cases could be unified by defining convolution with respect to a general positive measure on  $[0, \infty)$ . Moreover, the definition clearly makes sense for functions that are not necessarily probability density functions.

Suppose that  $f, g: [0, \infty) \to \mathbb{R}$  ae locally bounded and that H is a distribution function on  $[0, \infty)$ . The *convolution* of f and g with respect to H is the function on  $[0, \infty)$  defined by

$$t \mapsto \int_0^t f(t-s)g(s) \, dH(s) \tag{15.2.6}$$

If *f* and *g* are probability density functions for discrete distributions on a countable set  $C \subseteq [0, \infty)$  and if *H* is counting measure on *C*, we get discrete convolution, as above. If *f* and *g* are probability density functions for continuous distributions on  $[0, \infty)$  and if *H* is Lebesgue measure, we get continuous convolution, as above. Note however, that if *g* is nonnegative then  $G(t) = \int_0^t g(s) dH(s)$  for  $t \in [0, \infty)$  defines another distribution function on  $[0, \infty)$ , and the convolution integral above is simply  $\int_0^t f(t-s) dG(s)$ . This motivates our next version of convolution, the one that we will use in the remainder of this section.

Suppose that  $f : [0, \infty) \to \mathbb{R}$  is locally bounded and that G is a distribution function on  $[0, \infty)$ . The convolution of the *function* f with the *distribution* G is the function f \* G defined by

$$(f * G)(t) = \int_0^t f(t - s) \, dG(s), \quad t \in [0, \infty)$$
(15.2.7)

Note that if *F* and *G* are distribution functions on  $[0, \infty)$ , the convolution F \* G makes sense, with *F* simply as a *function* and *G* as a *distribution function*. The result is another distribution function. Moreover in this case, the operation is *commutative*.

If *F* and *G* are distribution functions on  $[0, \infty)$  then F \* G is also a distribution function on  $[0, \infty)$ , and F \* G = G \* FProof

Let  $F \otimes G$  and  $G \otimes F$  denote the usual product measures on  $[0, \infty)^2 = [0, \infty) \times [0, \infty)$ . For  $t \in [0, \infty)$ , let  $T_t = \{(r, s) \in [0, \infty)^2 : r + s \le t\}$ , the triangular region with vertices (0, 0), (t, 0), and (0, t). Then

$$(F * G)(t) = \int_0^t F(t - s) \, dG(s) = \int_0^t \int_0^{t - s} dF(r) \, dG(s) = (F \otimes G) \, (T_t) \tag{15.2.8}$$

This clearly defines a distribution function. Specifically, if  $0 \le s \le t < \infty$  then  $T_s \subseteq T_t$  so  $(F * G)(s) = (F \otimes G)(T_s) \le (F \otimes G)(T_t) = (F * G)(t)$ . Hence F \* G is decreasing. If  $t \in [0, \infty)$  and  $t_n \in [0, \infty)$  for  $n \in \mathbb{N}_+$  with  $t_n \downarrow t$  as  $n \to \infty$  then  $T_{t_n} \downarrow T_t$  (in the subset sense) as  $n \to \infty$  so by the continuity property of  $F \otimes G$  we have  $(F * G)(t_n) = (F \otimes G)(T_{t_n}) \downarrow (F \otimes G)(T_t) = (F * G)(t)$  as  $n \to \infty$ . Hence F \* G is continuous from the right.

For the commutative property, we have  $(F * G)(t) = (F \otimes G)(T_t)$  and  $(G * F)(t) = (G \otimes F)(T_t)$ . By the symmetry of the triangle  $T_t$  with respect to the diagonal  $\{(s, s) : s \in [0, \infty)\}$ , these are the same.

If *F* and *G* are probability distribution functions corresponding to independent random variables *X* and *Y* with values in  $[0, \infty)$ , then F \* G is the probability distribution function of X + Y. Suppose now that  $f : [0, \infty) \to \mathbb{R}$  is locally bounded and that *G* and *H* are distribution functions on  $[0, \infty)$ . From the previous result, both (f \* G) \* H and f \* (G \* H) make sense. Fortunately, they are the same so that convolution is *associative*.

Suppose that  $f : [0, \infty) \to \mathbb{R}$  is locally bounded and that *G* and *H* are distribution functions on  $[0, \infty)$ . Then

$$(f * G) * H = f * (G * H)$$
(15.2.9)

Proof

For  $t\in [0,\infty)$ ,

$$[(f * G) * H](t) = \int_0^t (f * G)(t - s) \, dH(s) = \int_0^t \int_0^{t - s} f(t - s - r) \, dG(r) \, dH(s) = [f * (G * H)](t)$$
(15.2.10)

Finally, convolution is a *linear operation*. That is, convolution preserves sums and scalar multiples, whenever these make sense.

Suppose that  $f, g: [0, \infty) \to \mathbb{R}$  are locally bounded, H is a distribution function on  $[0, \infty)$ , and  $c \in \mathbb{R}$ . Then 1. (f+g) \* H = (f \* H) + (g \* H)

2. (cf) \* H = c(f \* H)

Proof

These properties follow easily from linearity properties of the integral.

1. 
$$[(f+g)*H](t) = \int_0^t (f+g)(t-s) \, dH(s) = \int_0^t f(t-s) \, dH(s) + \int_0^t g(t-s) \, dH(s) = (f*H)(t) + (g*H)(t)$$
  
2. 
$$[(cf)*H](t) = \int_0^t cf(t-s) \, dH(s) = c \int_0^t f(t-s) \, dH(s) = c(f*H)(t)$$

Suppose that  $f:[0,\infty) \to \mathbb{R}$  is locally bounded, G and H are distribution functions on  $[0,\infty)$ , and that  $c \in (0,\infty)$ . Then

1. f \* (G + H) = (f \* G) + (f \* H)2. f \* (cG) = c(f \* G)

Proof

These properties also follow from linearity properties of the integral.

1. 
$$[f * (G+H)](t) = \int_0^t f(t-s) d(G+H)(s) = \int_0^t f(t-s) dG(s) + \int_0^t f(t-s) dH(s) = (f * G)(t) + (f * H)(t)$$
  
2.  $[f * (cG)](t) = \int_0^t f(t-s) d(cG)(s) = c \int_0^t f(t-s) dG(s) = c(f * G)(t)$ 

#### Laplace Transforms

Like convolution, the term *Laplace transform* (named for Pierre Simon Laplace of course) can mean slightly different things in different settings. We start with the usual definition that you may have seen in your study of differential equations or other subjects:

The *Laplace transform* of a *function*  $f : [0, \infty) \to \mathbb{R}$  is the function  $\phi$  defined as follows, for all  $s \in (0, \infty)$  for which the integral exists in  $\mathbb{R}$ :

$$\phi(s) = \int_0^\infty e^{-st} f(t) \, dt \tag{15.2.11}$$

Suppose that f is nonnegative, so that the integral defining the transform exists in  $[0, \infty]$  for every  $s \in (0, \infty)$ . If  $\phi(s_0) < \infty$  for some  $s_0 \in (0, \infty)$  then  $\phi(s) < \infty$  for  $s \ge s_0$ . The transform of a general function f exists (in  $\mathbb{R}$ ) if and only if the transform of |f| is finite at s. It follows that if f has a Laplace transform, then the transform  $\phi$  is defined on an interval of the form  $(a, \infty)$  for some  $a \in (0, \infty)$ . The

actual domain is of very little importance; the main point is that the Laplace transform, if it exists, will be defined for all sufficiently large *s*. Basically, a nonnegative function will fail to have a Laplace transform if it grows at a "hyper-exponential rate" as  $t \to \infty$ .

We could generalize the Laplace transform by replacing the Riemann or Lebesgue integral with the integral over a positive measure on  $[0, \infty)$ .

Suppose that that *G* is a distribution on  $[0, \infty)$ . The Laplace transform of  $f : [0, \infty) \to \mathbb{R}$  with respect to *G* is the function given below, defined for all  $s \in (0, \infty)$  for which the integral exists in  $\mathbb{R}$ :

$$s \mapsto \int_0^\infty e^{-st} f(t) \, dG(t) \tag{15.2.12}$$

However, as before, if f is nonnegative, then  $H(t) = \int_0^t f(x) dG(x)$  for  $t \in [0, \infty)$  defines another distribution function, and the previous integral is simply  $\int_0^\infty e^{-st} dH(t)$ . This motivates the definiton for the Laplace transform of a distribution.

The *Laplace transform* of a *distribution* F on  $[0, \infty)$  is the function  $\Phi$  defined as follows, for all  $s \in (0, \infty)$  for which the integral is finite:

$$\Phi(s) = \int_0^\infty e^{-st} dF(t)$$
 (15.2.13)

Once again if *F* has a Laplace transform, then the transform will be defined for all sufficiently large  $s \in (0, \infty)$ . We will try to be explicit in explaining which of the Laplace transform definitions is being used. For a generic function, the first definition applies, and we will use a lower case Greek letter. If the function is a *distribution function*, either definition makes sense, but it is usually the the latter that is appropriate, in which case we use an upper case Greek letter. Fortunately, there is a simple relationship between the two.

Suppose that F is a distribution function on  $[0, \infty)$ . Let  $\Phi$  denote the Laplace transform of the *distribution* F and  $\phi$  the Laplace transform of the *function* F. Then  $\Phi(s) = s\phi(s)$ .

Proof

The main tool is Fubini's theorem (named for Guido Fubini), which allow us to interchange the order of integration for a nonnegative function.

$$\phi(s) = \int_0^\infty e^{-st} F(t) \, dt = \int_0^\infty e^{-st} \left( \int_0^t dF(x) \right) dt \tag{15.2.14}$$

$$= \int_0^\infty \left( \int_x^\infty e^{-st} dt \right) dF(x) = \int_0^\infty \frac{1}{s} e^{-sx} dF(x) = \frac{1}{s} \Phi(s)$$
(15.2.15)

For a probability distribution, there is also a simple relationship between the Laplace transform and the moment generating function.

Suppose that *X* is a random variable with values in  $[0, \infty)$  and with probability distribution function *F*. The Laplace transform  $\Phi$  and the moment generating function  $\Gamma$  of the distribution *F* are given as follows, and so  $\Phi(s) = \Gamma(-s)$  for all  $s \in (0, \infty)$ .

$$\Phi(s) = \mathbb{E}\left(e^{-sX}\right) = \int_0^\infty e^{-st} dF(t)$$
(15.2.16)

$$\Gamma(s) = \mathbb{E}\left(e^{sX}\right) = \int_0^\infty e^{st} dF(t)$$
(15.2.17)

In particular, a probability distribution F on  $[0, \infty)$  always has a Laplace transform  $\Phi$ , defined on  $(0, \infty)$ . Note also that if F(0) < 1 (so that X is not deterministically 0), then  $\Phi(s) < 1$  for  $s \in (0, \infty)$ .

Laplace transforms are important for general distributions on  $[0, \infty)$  for the same reasons that moment generating functions are important for probability distributions: the transform of a distribution uniquely determines the distribution, and the transform of a convolution is the product of the corresponding transforms (and products are much nicer mathematically than convolutions). The following theorems give the essential properties of Laplace transforms. We assume that the transforms exist, of course, and it should be understood that equations involving transforms hold for sufficiently large  $s \in (0, \infty)$ .

Suppose that *F* and *G* are distributions on  $[0, \infty)$  with Laplace transforms  $\Phi$  and  $\Gamma$ , respectively. If  $\Phi(s) = \Gamma(s)$  for *s* sufficiently large, then G = H

In the case of general functions on  $[0, \infty)$ , the conclusion is that f = g except perhaps on a subset of  $[0, \infty)$  of measure 0. The Laplace transform is a linear operation.

Suppose that  $f, g: [0, \infty) \to \mathbb{R}$  have Laplace transforms  $\phi$  and  $\gamma$ , respectively, and  $c \in \mathbb{R}$  then

1. f + g has Laplace transform  $\phi + \gamma$ 

2. cf has Laplace transform  $c\phi$ 

Proof

These properties follow from the linearity of the integral. For s sufficiently large,

$$\begin{aligned} &1. \ \int_0^\infty e^{-st} \left[ f(t) + g(t) \right] dt = \int_0^\infty e^{-st} f(t) \, dt + \int_0^\infty e^{-st} g(t) \, dt = \phi(s) + \gamma(s) \\ &2. \ \int_0^\infty e^{-st} c f(t) \, dt = c \int_0^\infty e^{-st} f(t) \, dt = c \phi(s) \end{aligned}$$

The same properties holds for distributions on  $[0, \infty)$  with  $c \in (0, \infty)$ . Integral transforms have a smoothing effect. Laplace transforms are differentiable, and we can interchange the derivative and integral operators.

Suppose that  $f:[0,\infty) \to \mathbb{R}$  has Lapalce transform  $\phi$ . Then  $\phi$  has derivatives of all orders and

$$\phi^{(n)}(s) = \int_0^\infty (-1)^n t^n e^{-st} f(t) \, dt \tag{15.2.18}$$

Restated,  $(-1)^n \phi^{(n)}$  is the Laplace transform of the function  $t \mapsto t^n f(t)$ . Again, one of the most important properties is that the Laplace transform turns convolution into products.

Suppose that  $f : [0, \infty) \to \mathbb{R}$  is locally bounded with Laplace transform  $\phi$ , and that G is a distribution function on  $[0, \infty)$  with Laplace transform  $\Gamma$ . Then f \* G has Laplace transform  $\phi \cdot \Gamma$ .

Proof

By definition, the Laplace transform of f \* G is

$$\int_{0}^{\infty} e^{-st} (f * G)(t) dt = \int_{0}^{\infty} e^{-st} \left( \int_{0}^{t} f(t - x) dG(x) \right) dt$$
(15.2.19)

Writing  $e^{-st} = e^{-s(t-x)} e^{-sx}$  and reversing the order of integration, the last iterated integral can be written as

$$\int_{0}^{\infty} e^{-sx} \left( \int_{x}^{\infty} e^{-s(t-x)} f(t-x) dt \right) dG(x)$$
(15.2.20)

The interchange is justified, once again, by Fubini's theorem, since our functions are integrable (for sufficiently large  $s \in (0, \infty)$ ). Finally with the substitution y = t - x the last iterated integral can be written as a product

$$\left(\int_0^\infty e^{-sy} f(y) \, dy\right) \left(\int_0^\infty e^{-sx} dG(x)\right) = \phi(s)\Gamma(s) \tag{15.2.21}$$

If *F* and *G* are distributions on  $[0, \infty)$ , then so is F \* G. The result above applies, of course, with *F* and F \* G thought of as *functions* and *G* as a *distribution*, but multiplying through by *s* and using the theorem above, it's clear that the result is also true with all three as distributions.

#### **Renewal Equations and Their Solutions**

Armed with our new analytic machinery, we can return to the study of renewal processes. Thus, suppose that we have a renewal process with interarrival sequence  $\mathbf{X} = (X_1, X_2, ...)$ , arrival time sequence  $\mathbf{T} = (T_0, T_1, ...)$ , and counting process  $\mathbf{N} = \{N_t : t \in [0, \infty)\}$ . As usual, let F denote the common distribution function of the interarrival times, and let M denote the renewal function, so that  $M(t) = \mathbb{E}(N_t)$  for  $t \in [0, \infty)$ . Of course, the probability distribution function F defines a probability measure on  $[0, \infty)$ , but as noted earlier, M is also a distribution functions and so defines a positive measure on  $[0, \infty)$ . Recall that  $F^c = 1 - F$  is the right distribution function (or reliability function) of an interarrival time.

The distributions of the arrival times are the convolution powers of F. That is,  $F_n = F^{*n} = F * F * \cdots * F$ .

Proof

This follows from the definitions:  $F_n$  is the distribution function of  $T_n$ , and  $T_n = \sum_{i=1}^n X_i$ . Since X is an independent, identically distributed sequence,  $F_n = F^{*n}$ 

The next definition is the central one for this section.

Suppose that  $a:[0,\infty) o\mathbb{R}$  is locally bounded. An integral equation of the form

$$u = a + u * F \tag{15.2.22}$$

for an unknown function  $u : [0, \infty) \to \mathbb{R}$  is called a *renewal equation* for u.

Often  $u(t) = \mathbb{E}(U_t)$  where  $\{U_t : t \in [0, \infty)\}$  is a random process of interest associated with the renewal process. The renewal equation comes from conditioning on the first arrival time  $T_1 = X_1$ , and then using the defining property of the renewal process—the fact that the process starts over, interdependently of the past, at the arrival time. Our next important result illustrates this.

Renewal equations for M and F:

1. M = F + M \* F

2. 
$$F = M - F * M$$

Proof

1. We condition on the time of the first arrival  $X_1$  and break the domain of integration  $[0, \infty)$  into the two parts [0, t] and  $(t, \infty)$ :

$$M(t) = \mathbb{E}(N_t) = \int_0^\infty E(N_t \mid X_1 = s) \, dF(s) = \int_0^t \mathbb{E}(N_t \mid X_1 = s) \, dF(s) + \int_t^\infty \mathbb{E}(N_t \mid X_1 = s) \, dF(s) \quad (15.2.23)$$

If s > t then  $\mathbb{E}(N_t \mid X_1 = s) = 0$ . If  $0 \le s \le t$ , then by the renewal property,  $\mathbb{E}(N_t \mid X_1 = s) = 1 + M(t - s)$ . Hence we have

$$M(t) = \int_0^t [1 + M(t - s)] \, dF(s) = F(t) + (M * F)(t) \tag{15.2.24}$$

2. From (a) and the commutative property of convolution given above (recall that M is also a distribution function), we have F = M - M \* F = M - F \* M

Thus, the renewal function itself satisfies a renewal equation. Of course, we already have a "formula" for M, namely  $M = \sum_{n=1}^{\infty} F_n$ . However, sometimes M can be computed more easily from the renewal equation directly. The next result is the transform version of the previous result:

The distributions F and M have Laplace transfroms  $\Phi$  and  $\Gamma$ , respectively, that are related as follows:

$$\Gamma = \frac{\Phi}{1 - \Phi}, \quad \Phi = \frac{\Gamma}{\Gamma + 1} \tag{15.2.25}$$

Proof from the renewal equation

Taking Laplace transforms through the renewal equation M = F + M \* F (and treating all terms as distributions), we have  $\Gamma = \Phi + \Gamma \Phi$ . Solving for  $\Gamma$  gives the result. Recall that since F is a probability distribution on  $[0, \infty)$  with F(0) < 1, we know that  $0 < \Phi(s) < 1$  for  $s \in (0, \infty)$ . The second equation follows from the first by simple algebra.

Proof from convolution

Recall that  $M = \sum_{n=1}^{\infty} F^{*n}$ . Taking Laplace trasforms (again treating all terms as distributions), and using geometric series we have

$$\Gamma = \sum_{n=1}^{\infty} \Phi^n = \frac{\Phi}{1 - \Phi}$$
(15.2.26)

Recall again that  $0 < \Phi(s) < 1$  for  $s \in (0, \infty)$ . Once again, the second equation follows from the first by simple algebra.

In particular, the renewal distribution M always has a Laplace transform. The following theorem gives the fundamental results on the solution of the renewal equation.

Suppose that  $a: [0, \infty) \to \mathbb{R}$  is locally bounded. Then the unique locally bounded solution to the renewal equation u = a + u \* F is u = a + a \* M.

Direct proof

Suppose that u = a + a \* M. Then u \* F = a \* F + a \* M \* F. But from the renewal equation for M above, M \* F = M - F. Hence we have u \* F = a \* F + a \* (M - F) = a \* [F + (M - F)] = a \* M. But a \* M = u - a by definition of u, so u = a + u \* F and hence u is a solution to the renewal equation. Next since a is locally bounded, so is u = a + a \* M. Suppose now that v is another locally bounded solution of the integral equation, and let w = u - v. Then w is locally bounded and

w \* F = (u \* F) - (v \* F) = [(u - a) - (v - a) = u - v = w. Hence  $w = w * F_n$  for  $n \in \mathbb{N}_+$ . Suppose that  $|w(s)| \le D_t$  for  $0 \le s \le t$ . Then  $|w(t)| \le D_t F_n(t)$  for  $n \in \mathbb{N}_+$ . Since  $M(t) = \sum_{n=1}^{\infty} F_n(t) < \infty$  it follows that  $F_n(t) \to 0$  as  $n \to \infty$ . Hence w(t) = 0 for  $t \in [0, \infty)$  and so u = v.

## Proof from Laplace transforms

Let  $\alpha$  and  $\theta$  denote the Laplace transforms of the functions a and u, respectively, and  $\Phi$  the Laplace transform of the distribution F. Taking Laplace transforms through the renewal equations gives the simple algebraic equation  $\theta = \alpha + \theta \Phi$ . Solving give

$$\theta = \frac{\alpha}{1 - \Phi} = \alpha \left( 1 + \frac{\Phi}{1 - \Phi} \right) = \alpha + \alpha \Gamma$$
(15.2.27)

where  $\Gamma = \frac{\Phi}{1-\Phi}$  is the Laplace transform of the distribution *M*. Thus  $\theta$  is the transform of a + a \* M.

Returning to the renewal equations for M and F above, we now see that the renewal function M completely determines the renewal process: from M we can obtain F, and everything is ultimately constructed from the interarrival times. Of course, this is also clear from the Laplace transform result above which gives simple algebraic equations for each transform in terms of the other.

#### The Distribution of the Age Variables

Let's recall the definition of the age variables. A deterministic time  $t \in [0, \infty)$  falls in the *random* renewal interval  $[T_{N_t}, T_{N_t+1})$ . The *current life* (or age) at time t is  $C_t = t - T_{N_t}$ , the *remaining life* at time t is  $R_t = T_{N_t+1} - t$ , and the *total life* at time t is  $L_t = T_{N_t+1} - T_{N_t}$ . In the usual reliability setting,  $C_t$  is the age of the device that is in service at time t, while  $R_t$  is the time until that device fails, and  $L_t$  is the total lifetime of the device.

For  $t, y \in [0, \infty)$ , let

$$r_y(t) = \mathbb{P}(R_t > y) = \mathbb{P}(N(t, t+y) = 0)$$
(15.2.28)

and let  $F_y^c(t) = F^c(t+y)$ . Note that  $y \mapsto r_y(t)$  is the right distribution function of  $R_t$ . We will derive and then solve a renewal equation for  $r_y$  by conditioning on the time of the first arrival. We can then find integral equations that describe the distribution of the current age and the joint distribution of the current and remaining ages.

For  $y \in [0, \infty)$ ,  $r_y$  satisfies the renewal equation  $r_y = F_y^c + r_y * F$  and hence for  $t \in [0, \infty)$ ,

$$\mathbb{P}(R_t > y) = F^c(t+y) + \int_0^t F^c(t+y-s) \, dM(s), \quad y \ge 0 \tag{15.2.29}$$

Proof

As usual, we condition on the time of the first renewal:

$$\mathbb{P}(R_t > y) = \int_0^\infty \mathbb{P}(R_t > y \mid X_1 = s) \, dF(s) \tag{15.2.30}$$

We are naturally led to break the domain  $[0, \infty)$  of the integral into three parts [0, t], (t, t + y], and  $(t + y, \infty)$ , which we take one at a time.

Note first that  $\mathbb{P}(R_t > y \mid X_1 = s) = \mathbb{P}(R_{t-s} > y)$  for  $s \in [0, t]$ 

The event 
$$R_t > y$$
 given  $X_1 = s$  when  $0 \le s \le t$ 

Next note that  $\mathbb{P}(R_t > y \mid X_1 = s) = 0 ~~ ext{for}~ s \in (t,t+y]$ 

The event 
$$R_t > y$$
 given  $X_1 = s$  when  $t < s \le t + y$ 

Finally note that  $\mathbb{P}(R_t > y \mid X_1 = s) = 1$  for  $s \in (t + y, \infty)$ 

The event 
$$R_t > y$$
 given  $X_1 = s$  when  $s > t + y$   ${\mathbb Z}_{\operatorname{Age3,png}}$ 

Putting the pieces together we have

$$\mathbb{P}(R_t > y) = \int_0^t \mathbb{P}(R_{t-s} > y) \, dF(s) + \int_t^{t+y} 0 \, dF(s) + \int_{t+y}^\infty 1 \, dF(s) \tag{15.2.31}$$

In terms of our function notation, the first integral is  $(r_y * F)(t)$ , the second integral is 0 of course, and the third integral is  $1 - F(t+y) = F_y^c(t)$ . Thus the renewal equation is satisfied and the formula for  $\mathbb{P}(R_t > y)$  follows the fundamental theorem on

#### renewal equations.

We can now describe the distribution of the current age.

For  $t \in [0, \infty)$ ,

$$\mathbb{P}(C_t \ge x) = F^c(t) + \int_0^{t-x} F^c(t-s) \, dM(s), \quad x \in [0,t] \tag{15.2.32}$$

Proof

This follows from the previous theorem and the fact that  $\mathbb{P}(C_t \geq x) = \mathbb{P}(R_{t-x} > x)$  for  $x \in [0,t]$ .

Finally we get the joint distribution of the current and remaining ages.

For  $t\in [0,\infty)$ ,

$$\mathbb{P}(C_t \ge x, R_t > y) = F^c(t+y) + \int_0^{t-x} F^c(t+y-s) \, dM(s), \quad x \in [0,t], \; y \in [0,\infty)$$
 (15.2.33)

Proof

Recall that  $\mathbb{P}(C_t \ge x, R_t > y) = \mathbb{P}(R_{t-x} > x + y)$  . The result now follows from the result above for the remaining life.

## **Examples and Special Cases**

#### Uniformly Distributed Interarrivals

Consider the renewal process with interarrival times uniformly distributed on [0, 1]. Thus the distribution function of an interarrival time is F(x) = x for  $0 \le x \le 1$ . The renewal function M can be computed from the general renewal equation for M by successively solving differential equations. The following exercise give the first two cases.

On the interval [0, 2], show that *M* is given as follows:

1.  $M(t) = e^t - 1$  for  $0 \le t \le 1$ 2.  $M(t) = (e^t - 1) - (t - 1)e^{t - 1}$  for  $1 \le t \le 2$ Solution

Figure 15.2.2: The graph of M on the interval [0, 2]

Show that the Laplace transform  $\Phi$  of the interarrival distribution F and the Laplace transform  $\Gamma$  of the renewal distribution M are given by

$$\Phi(s) = \frac{1 - e^{-s}}{s}, \ \Gamma(s) = \frac{1 - e^{-s}}{s - 1 + e^{-s}}; \quad s \in (0, \infty)$$
(15.2.34)

Solution

First note that

$$\Phi(s) = \int_0^\infty e^{-st} dF(t) = \int_0^1 e^{-st} dt = \frac{1 - e^{-s}}{s}, \quad s \in (0, \infty)$$
(15.2.35)

The formula for  $\Gamma$  follows from  $\Gamma = \Phi/(1-\Phi)$  .

Open the renewal experiment and select the uniform interarrival distribution on the interval [0, 1]. For each of the following values of the time parameter, run the experiment 1000 times and note the shape and location of the empirical distribution of the counting variable.

$1.\iota$	= 0
2. <i>t</i>	= 10
3. t	= 15
4. <i>t</i>	= 20
5. <i>t</i>	= 25
6. <i>t</i>	= 30

## The Poisson Process

Recall that the Poisson process has interarrival times that are exponentially distributed with rate parameter r > 0. Thus, the interarrival distribution function F is given by  $F(x) = 1 - e^{-rx}$  for  $x \in [0, \infty)$ . The following exercises give alternate proofs of fundamental results obtained in the Introduction.

Show that the renewal function *M* is given by M(t) = rt for  $t \in [0, \infty)$ 

- 1. Using the renewal equation
- 2. Using Laplace transforms

Solution

1. The renewal equation gives

$$M(t) = 1 - e^{-rt} + \int_0^t M(t-s)r e^{-rs} \, ds \tag{15.2.36}$$

Substituting x = t - s in the integral gives

$$M(t) = 1 - e^{-rt} + re^{-rt} \int_0^t M(x) e^{rx} dx$$
(15.2.37)

Multiplying through by  $e^{rt}$ , differentiating with respect to t, and simplifying gives M'(t) = r for  $t \ge 0$ . Since M(0) = 0, the result follows.

2. The Laplace transform  $\Phi$  of the distribution F is given by

$$\Phi(s) = \int_0^\infty e^{-st} r e^{-rt} dt = \int_0^\infty r n e^{-(s+r)t} dt = \frac{r}{r+s}, \quad s \in (0,\infty)$$
(15.2.38)

So the Laplace transform  $\Gamma$  of the distribution *M* is given by

$$\Gamma(s) = rac{\Phi(s)}{1 - \Phi(s)} = rac{r}{s}, \quad s \in (0, \infty)$$
(15.2.39)

But this is the Laplace transform of the distribution  $t \mapsto rt$ .

Show that the current and remaining life at time  $t \ge 0$  satisfy the following properties:

- 1.  $C_t$  and  $R_t$  are independent.
- 2.  $R_t$  has the same distribution as an interarrival time, namely the exponential distribution with rate parameter r.
- 3.  $C_t$  has a truncated exponential distribution with parameters t and r:

$$\mathbb{P}(C_t \ge x) = \begin{cases} e^{-rx}, & 0 \le x \le t \\ 0, & x > t \end{cases}$$
(15.2.40)

Solution

Recall again that M(t) = rt for  $t \in [0, \infty)$ . Using the result above on the joint distribution of the current and remaining life, and some standard calculus, we have

$$\mathbb{P}(C_t \ge x, R_t \ge y) = e^{-r(t+y)} + \int_0^{t-x} e^{-r(t+y-s)} r ds = r^{-rx} e^{-ry}, \quad x \in [0,t], \ y \in [0,\infty)$$
(15.2.41)

Letting y = 0 gives  $\mathbb{P}(C_t \ge x) = e^{-rx}$  for  $x \in [0, t]$ . Letting x = 0 gives  $\mathbb{P}(R_t \ge y) = e^{-ry}$  for  $y \in [0, \infty)$ . But then also  $\mathbb{P}(C_t \ge x, R_t \ge y) = \mathbb{P}(C_t \ge x)\mathbb{P}(R_t \ge y)$  for  $x \in [0, t]$  and  $y \in [0, \infty)$  so the variables are independent.

### **Bernoulli Trials**

Consider the renewal process for which the interarrival times have the geometric distribution with parameter p. Recall that the probability density function is

$$f(n)=(1-p)^{n-1}p, \quad n\in\mathbb{N}_+$$
 (15.2.42)

The arrivals are the successes in a sequence of Bernoulli trials. The number of successes  $Y_n$  in the first n trials is the counting variable for  $n \in \mathbb{N}$ . The renewal equations in this section can be used to give alternate proofs of some of the fundamental results in the Introduction.

Show that the renewal function is M(n) = np for  $n \in \mathbb{N}$ 

1. Using the renewal equation

2. Using Laplace transforms

Proof

1. The renewal equation for M is

$$M(n)=F(n)+(M*F)(n)=1-(1-p)^n+\sum_{k=1}^n M(n-k)p(1-p)^{k-1},\quad n\in\mathbb{N}$$
 (15.2.43)

So substituting values of n successively we have

$$M(0) = 1 - (1 - p)^0 = 0 (15.2.44)$$

$$M(1) = 1 - (1 - p) + M(0)p = p$$
(15.2.45)

$$M(2) = 1 - (1 - p)^{2} + M(1)p + M(0)p(1 - p) = 2p$$
(15.2.46)

and so forth.

2. The Laplace transform  $\Phi$  of the distribution F is

$$\Phi(s) = \sum_{n=1}^{\infty} e^{-sn} p (1-p)^{n-1} = \frac{p e^{-s}}{1 - (1-p) e^{-s}}, \quad s \in (0,\infty)$$
(15.2.47)

Hence the Laplace transform of the distribution M is

$$\Gamma(s) = \frac{\Phi(s)}{1 - \Phi(s)} = p \frac{e^{-s}}{1 - e^{-s}}, \quad s \in (0, \infty)$$
(15.2.48)

But  $s\mapsto e^{-s}/(1-e^{-s})\,$  is the transform of the distribution  $n\mapsto n\,$  on  $\mathbb N.$  That is,

$$\sum_{n=1}^{\infty} e^{-sn} \cdot 1 = \frac{e^{-s}}{1 - e^{-s}}, \quad s \in (0, \infty)$$
(15.2.49)

Show that the current and remaining life at time  $n \in \mathbb{N}$  satisfy the following properties:.

1.  $C_n$  and  $R_n$  are independent.

2.  $R_n$  has the same distribution as an interarrival time, namely the geometric distribution with parameter p.

3.  $C_n$  has a truncated geometric distribution with parameters n and p:

$$\mathbb{P}(C_n = j) = \begin{cases} p(1-p)^j, & j \in \{0, 1, \dots, n-1\}\\ (1-p)^n, & j = n \end{cases}$$
(15.2.50)

Solution

Recall again that M(n) = pn for  $n \in \mathbb{N}$ . Using the result above on the joint distribution of the current and remaining life and geometric series, we have

$$\mathbb{P}(C_n \ge j, R_n > k) = (1-p)^{n+k} + \sum_{i=1}^{n-j} p(1-p)^{n+k-i} = (1-p)^{j+k}, \quad j \in \{0, 1, \dots, n\}, \ k \in \mathbb{N}$$
 (15.2.51)

Letting k = 0 gives  $\mathbb{P}(C_n \ge j) = (1-p)^j$  for  $j \in \{0, 1, \dots, n\}$ . Letting j = 0 gives  $\mathbb{P}(R_n > k) = (1-p)^k$  for  $k \in \mathbb{N}$ . But then also  $\mathbb{P}(C_n \ge j, R_n > k) = \mathbb{P}(C_n \ge j)\mathbb{P}(R_n > k)$  for  $j \in \{0, 1, \dots, n\}$  and  $k \in \mathbb{N}$  so the variables are independent.

#### A Gamma Interarrival Distribution

Consider the renewal process whose interarrival distribution F is gamma with shape parameter 2 and rate parameter  $r \in (0, \infty)$ . Thus

$$F(t) = 1 - (1 + rt)e^{-rt}, \quad t \in [0, \infty)$$
 (15.2.52)

Recall also that F is the distribution of the sum of two independent random variables, each having the exponential distribution with rate parameter r.

Show that the renewal distribution function M is given by

$$M(t) = -rac{1}{4} + rac{1}{2}rt + rac{1}{4}e^{-2rt}, \quad t \in [0,\infty)$$
 (15.2.53)

Solution

The exponential distribution with rate parameter r has Laplace transform  $s \mapsto r/(r+s)$  and hence the Laplace transform  $\Phi$  of the interarrival distribution F is given by

$$\Phi(s) = \left(\frac{r}{r+s}\right)^2 \tag{15.2.54}$$

So the Laplace transform  $\Gamma$  of the distribution M is

$$\Gamma(s) = \frac{\Phi(s)}{1 - \Phi(s)} = \frac{r^2}{s(s + 2r)}$$
(15.2.55)

Using a partial fraction decomposition,

$$\Gamma(s) = \frac{r}{2s} - \frac{r}{2(s+2r)} = \frac{1}{2}\frac{r}{s} - \frac{1}{4}\frac{2r}{s+2r}$$
(15.2.56)

But the r/s is the Laplace transform of the distribution rt and 2r/(s+2r) is the Laplace transform of the distribution  $1 - e^{-2rt}$  (the exponential distribution with parameter 2r).

Note that  $M(t) pprox - rac{1}{4} + rac{1}{2} rt \;\; ext{as} \; t o \infty.$ 

Open the renewal experiment and select the gamma interarrival distribution with shape parameter k = 2 and scale parameter b = 1 (so the rate parameter  $r = \frac{1}{b}$  is also 1). For each of the following values of the time parameter, run the experiment 1000 times and note the shape and location of the empirical distribution of the counting variable.

1. t = 52. t = 103. t = 154. t = 205. t = 256. t = 30

# 15.3: Renewal Limit Theorems

We start with a renewal process as constructed in the introduction. Thus,  $\mathbf{X} = (X_1, X_2, ...)$  is the sequence of interarrival times. These are independent, identically distributed, nonnegative variables with common distribution function F (satisfying F(0) < 1) and common mean  $\mu$ . When  $\mu = \infty$ , we let  $1/\mu = 0$ . When  $\mu < \infty$ , we let  $\sigma$  denote the common standard deviation. Recall also that  $F^c = 1 - F$  is the right distribution function (or reliability function). Then,  $\mathbf{T} = (T_0, T_1, ...)$  is the arrival time sequence, where  $T_0 = 0$  and

$$T_n = \sum_{i=1}^n X_i$$
 (15.3.1)

is the time of the *n*th arrival for  $n \in \mathbb{N}_+$ . Finally,  $N = \{N_t : t \in [0, \infty)\}$  is the counting process, where for  $t \in [0, \infty)$ ,

$$N_t = \sum_{n=1}^{\infty} \mathbf{1}(T_n \le t)$$
 (15.3.2)

is the number of arrivals in [0, t]. The renewal function M is defined by  $M(t) = \mathbb{E}(N_t)$  for  $t \in [0, \infty)$ .

We noted earlier that the arrival time process and the counting process are inverses, in a sense. The arrival time process is the partial sum process for a sequence of independent, identically distributed variables. Thus, it seems reasonable that the fundamental limit theorems for partial sum processes (the law of large numbers and the central limit theorem theorem), should have analogs for the counting process. That is indeed the case, and the purpose of this section is to explore the limiting behavior of renewal processes. The main results that we will study, known appropriately enough as *renewal theorems*, are important for other stochastic processes, particularly Markov chains.

## **Basic Theory**

#### The Law of Large Numbers

Our first result is a strong law of large numbers for the renewal counting process, which comes as you might guess, from the law of large numbers for the sequence of arrival times.

If  $\mu < \infty$  then  $N_t/t o 1/\mu$  as  $t o \infty$  with probability 1.

Proof

Recall that  $T_{N_t} \leq t < T_{N_t+1} \;\; ext{for} \; t > 0$  . Hence, if  $N_t > 0$  ,

$$\frac{T_{N_t}}{N_t} \le \frac{t}{N_t} < \frac{T_{N_t+1}}{N_t}$$
(15.3.3)

Recall that  $N_t \to \infty$  as  $t \to \infty$  with probability 1. Recall also that by the strong law of large numbers that  $T_n/n \to \mu$  as  $n \to \infty$  with probability 1. It follows that  $T_{N_t}/N_t \to \mu$  as  $t \to \infty$  with probability 1. Also,  $(N_t+1)/N_t \to 1$  as  $t \to \infty$  with probability 1. Therefore

$$\frac{T_{N_t+1}}{N_t} = \frac{T_{N_t+1}}{N_t+1} \frac{N_t+1}{N_t} \to \mu$$
(15.3.4)

as  $t o \infty$  with probability 1. Hence by the squeeze theorem for limits,  $t/N_t o \mu$  as  $t o \infty$  with probability 1.

Thus,  $1/\mu$  is the limiting average rate of arrivals per unit time.

Open the renewal experiment and set t = 50. For a variety of interarrival distributions, run the simulation 1000 times and note how the empirical distribution is concentrated near  $t/\mu$ .

#### The Central Limit Theorem

Our next goal is to show that the counting variable  $N_t$  is asymptotically normal.

Suppose that  $\mu$  and  $\sigma$  are finite, and let

$$Z_t = \frac{N_t - t/\mu}{\sigma\sqrt{t/\mu^3}}, \quad t > 0$$
(15.3.5)

The distribution of  $Z_t$  converges to the standard normal distribution as  $t o \infty$  . Proof

For  $n \in \mathbb{N}_+$  , let

$$W_n = \frac{T_n - n\mu}{\sigma\sqrt{n}} \tag{15.3.6}$$

The distribution of  $W_n$  converges to the standard normal distribution as  $n \to \infty$ , by the ordinary central limit theorem. Next, for  $z \in \mathbb{R}$ ,  $\mathbb{P}(Z_t \le z) = \mathbb{P}(T_{n(z,t)} > t)$  where  $n(z,t) = \lfloor t/\mu + z\sigma\sqrt{t/\mu^3} \rfloor$ . Also,  $\mathbb{P}(Z_t \le z) = \mathbb{P}[W_{n(z,t)} > w(z,t)]$  where

$$w(z,t) = -\frac{z}{\sqrt{1+z\sigma/\sqrt{t/\mu}}}$$
(15.3.7)

But  $n(z,t) \to \infty$  as  $t \to \infty$  and  $w(z,t) \to -z$  as  $t \to \infty$ . Recall that  $1 - \Phi(-z) = \Phi(z)$ , where as usual,  $\Phi$  is the standard normal distribution function. Thus, we conclude that  $\mathbb{P}(Z_t \leq z) \to \Phi(z)$  as  $t \to \infty$ .

Open the renewal experiment and set t = 50. For a variety of interarrival distributions, run the simulation 1000 times and note the "normal" shape of the empirical distribution. Compare the empirical mean and standard deviation to  $t/\mu$  and  $\sigma\sqrt{t/\mu^3}$ , respectively

#### The Elementary Renewal Theorem

The *elementary renewal theorem* states that the basic limit in the law of large numbers above holds in mean, as well as with probability 1. That is, the limiting mean average rate of arrivals is  $1/\mu$ . The elementary renewal theorem is of fundamental importance in the study of the limiting behavior of Markov chains, but the proof is not as easy as one might hope. In particular, recall that convergence with probability 1 does not imply convergence in mean, so the elementary renewal theorem does not follow from the law of large numbers.

#### $M(t)/t ightarrow 1/\mu$ as $t ightarrow\infty$ .

Proof

We first show that  $\liminf_{t\to\infty} M(t)/t \ge 1/\mu$ . Note first that this result is trivial if  $\mu = \infty$ , so assume that  $\mu < \infty$ . Next, recall that  $N_t + 1$  is a stopping time for the sequence of interarrival times X. Recall also that  $T_{N_t+1} > t$  for t > 0. From Wald's equation it follows that

$$\mathbb{E}(T_{N_t+1}) = \mathbb{E}(N_t+1)\mu = [M(t)+1]\mu > t$$
(15.3.8)

Therefore  $M(t)/t > 1/\mu - 1/t$  for t > 0. Hence  $\liminf_{t \to \infty} M(t)/t \ge 1/\mu$ .

Next we show that  $\limsup_{t\to\infty} M(t)/t \le 1/\mu$ . For this part of the proof, we need to *truncate* the arrival times, and use the basic comparison method. For a > 0, let

$$X_{a,i} = \begin{cases} X_i, & X_i \le a \\ a, & X_i > a \end{cases}$$
(15.3.9)

and consider the renewal process with the sequence of interarrival times  $X_a = (X_{a,1}, X_{a,2}, ...)$ . We will use the standard notation developed in the introductory section. First note that  $T_{a,N_{a,t}+1} \le t + a$  for t > 0 and a > 0. From Wald's equation again, it follows that  $[M_a(t) + 1] \mu_a \le t + a$ . Therefore

$$\frac{M_a(t)}{t} \le \left(\frac{1}{\mu_a} + \frac{a}{t\mu_a}\right) - \frac{1}{t}, \quad a, \ t > 0$$
(15.3.10)

But  $M(t) \leq M_a(t)$  for t > 0 and a > 0 and therefore

$$rac{M(t)}{t} \leq \left(rac{1}{\mu_a} + rac{a}{t\mu_a}
ight) - rac{1}{t}, \quad a, \ t > 0$$
 (15.3.11)

Hence  $\limsup_{t\to\infty} M(t)/t \le 1/\mu_a$  for a > 0. Finally,  $\mu_a \to \mu$  as  $a \to \infty$  by the monotone convergence theorem, so it follows that  $\limsup_{t\to\infty} M(t)/t \le 1/\mu$ 

Open the renewal experiment and set t = 50. For a variety of interarrival distributions, run the experiment 1000 times and once again compare the empirical mean and standard deviation to  $t/\mu$  and  $\sigma \sqrt{t/\mu^3}$ , respectively.

#### The Renewal Theorem

The *renewal theorem* states that the expected number of renewals in an interval is asymptotically proportional to the length of the interval; the proportionality constant is  $1/\mu$ . The precise statement is different, depending on whether the renewal process is arithmetic or not. Recall that for an arithmetic renewal process, the interarrival times take values in a set of the form  $\{nd : n \in \mathbb{N}\}$  for some  $d \in (0, \infty)$ , and the largest such d is the *span* of the distribution.

For h>0 ,  $M(t,t+h] o rac{h}{\mu}$  as  $t o \infty$  in each of the following cases:

- 1. The renewal process is non-arithmetic
- 2. The renewal process is arithmetic with span d, and h is a multiple of d

The renewal theorem is also known as *Blackwell's theorem* in honor of David Blackwell. The final limit theorem we will study is the most useful, but before we can state the theorem, we need to define and study the class of functions to which it applies.

#### **Direct Riemann Integration**

Recall that in the ordinary theory of Riemann integration, the integral of a function on the interval [0, t] exists if the upper and lower Riemann sums converge to a common number as the partition is refined. Then, the integral of the function on  $[0, \infty)$  is defined to be the limit of the integral on [0, t], as  $t \to \infty$ . For our new definition, a function is said to be *directly* Riemann integrable if the lower and upper Riemann sums on the entire unbounded interval  $[0, \infty)$  converge to a common number as the partition is refined, a more restrictive definition than the usual one.

Suppose that  $g: [0, \infty) \to [0, \infty)$ . For  $h \in [0, \infty)$  and  $k \in \mathbb{N}$ , let  $m_k(g, h) = \inf\{g(t) : t \in [kh, (k+1)h)\}$  and  $M_k(g, h) = \sup\{g(t) : t \in [kh, (k+1)h)\}$ . The lower and upper Riemann sums of g on  $[0, \infty)$  corresponding to h are

$$L_g(h) = h \sum_{k=0}^{\infty} m_k(g,h), \quad U_g(h) = h \sum_{k=0}^{\infty} M_k(g,h)$$
 (15.3.12)

The sums exist in  $[0, \infty]$  and satisfy the following properties:

1.  $L_g(h) \leq U_g(h)$  for h > 02.  $L_g(h)$  increases as h decreases 3.  $U_g(h)$  decreases as h decreases

It follows that  $\lim_{h\downarrow 0} L_g(h)$  and  $\lim_{h\downarrow 0} U_g(h)$  exist in  $[0,\infty]$  and  $\lim_{h\downarrow 0} L_g(h) \leq \lim_{h\downarrow 0} U_g(h)$ . Naturally, the case where the limits are finite and agree is what we're after.

A function  $g: [0, \infty) \to [0, \infty)$  is *directly Riemann integrable* if  $U_g(h) < \infty$  for every h > 0 and

$$\lim_{h \to 0} L_g(h) = \lim_{h \to 0} U_g(h) \tag{15.3.13}$$

The common value is  $\int_0^\infty g(t) dt$ .

Ordinary Riemann integrability on  $[0, \infty)$  allows functions that are unbounded and oscillate wildly as  $t \to \infty$ , and these are the types of functions that we want to exclude for the renewal theorems. The following result connects ordinary Riemann integrability with direct Riemann integrability.

# 

If  $g: [0, \infty) \to [0, \infty)$  is integrable (in the ordinary Riemann sense) on [0, t] for every  $t \in [0, \infty)$  and if  $U_g(h) < \infty$  for some  $h \in (0, \infty)$  then g is directly Riemann integrable.

Here is a simple and useful class of functions that are directly Riemann integrable.

Suppose that  $g:[0,\infty) \to [0,\infty)$  is decreasing with  $\int_0^\infty g(t)\,dt < \infty$  . Then g is directly Riemann integrable.

## The Key Renewal Theorems

The key renewal theorem is an integral version of the renewal theorem, and is the most useful of the various limit theorems.

Suppose that the renewal process is non-arithmetic and that  $g: [0, \infty) \to [0, \infty)$  is directly Riemann integrable. Then

$$(g*M)(t) = \int_0^t g(t-s) \, dM(s) \to \frac{1}{\mu} \int_0^\infty g(x) \, dx \text{ as } t \to \infty$$
 (15.3.14)

#### Connections

Our next goal is to see how the various renewal theorems relate.

The renewal theorem implies the elementary renewal theorem:

Proof

Let  $a_n = M(n, n+1]$  for  $n \in \mathbb{N}$ . From the renewal theorem,  $a_n \to 1/\mu$  as  $n \to \infty$ . Therefore  $\frac{1}{n} \sum_{k=0}^{n-1} a_k \to \frac{1}{\mu}$  as  $n \to \infty$ . It follows that  $M(n)/n \to 1/\mu$  as  $n \to \infty$ . But the renewal function is increasing so for t > 0,

$$\frac{\lfloor t \rfloor}{t} \frac{M(\lfloor t \rfloor)}{|t|} \le \frac{M(t)}{t} \le \frac{\lceil t \rceil}{t} \frac{M(\lceil t \rceil)}{\lceil t \rceil}$$
(15.3.15)

From the the squeeze theorem for limits it follows that  $M(t)/t \to 1/\mu$  as  $t \to \infty$ .

Conversely, the elementary renewal theorem *almost* implies the renewal theorem.

Proof

Assume that  $g(x) = \lim_{t\to\infty} [M(t+x) - M(t)]$  exists for each x > 0. (This assumption is the reason that the proof is incomplete.) Note that

$$M(t+x+y) - M(t) = [M(t+x+y) - M(t+x)] + [M(t+x) - M(t)]$$
(15.3.16)

Let  $t \to \infty$  to conclude that g(x+u) = g(x) + g(y) for all  $x \ge 0$  and  $y \ge 0$ . It follows that g is increasing and g(x) = cx for  $x \ge 0$  where c is a constant. Exactly as in the proof of the previous theorem, it follows that  $M(n)/n \to c$  as  $n \to \infty$ . From the elementary renewal theorem, we can conclude that  $c = 1/\mu$ .

The key renewal theorem implies the renewal theorem

#### Proof

This result follows by applying the key renewal theorem to the function  $g_h(x) = \mathbf{1}(0 \le x \le h)$  where h > 0.

Conversely, the renewal theorem implies the key renewal theorem.

#### The Age Processes

The key renewal theorem can be used to find the limiting distributions of the current and remaining age. Recall that for  $t \in [0, \infty)$  the current life at time t is  $C_t = t - T_{N_t}$  and the remaining life at time t is  $R_t = T_{N_t+1} - t$ .

If the renewal process is non-arithmetic, then

$$\mathbb{P}(R_t > x) o rac{1}{\mu} \int_x^\infty F^c(y) \, dy ext{ as } t o \infty, \quad x \in [0,\infty)$$

$$(15.3.17)$$

Proof

Recall that

$$\mathbb{P}(R_t > x) = F^c(t+x) + \int_0^t F^c(t+x-s) \, dM(s), \quad x \in [0,\infty)$$
 (15.3.18)

But  $F^c(t+x) \to 0$  as  $t \to \infty$ , and by the key renewal theorem, the integral converges to  $\frac{1}{\mu} \int_0^\infty F^c(x+y) \, dy$ . Finally a change of variables in the limiting integral gives the result.

If the renewal process is aperiodic, then

$$\mathbb{P}(R_t > x) o rac{1}{\mu} \int_x^\infty F^c(y) \, dy ext{ as } t o \infty, \quad x \in [0,\infty)$$
 (15.3.19)

Proof

Recall that, since the renewal process is aperiodic,

$$\mathbb{P}(C_t > x) = F^c(t) + \int_0^{t-x} F^c(t-s) \, dM(s), \quad x \in [0,t]$$
 (15.3.20)

Again,  $F^c(t) \to 0$  as  $t \to \infty$ . The change of variables u = t - x changes the integral into  $\int_0^u F^c(u + x - s) dM(s)$ . By the key renewal theorem, this integral converges  $\frac{1}{\mu} \int_0^\infty F^c(y + x) dy = \int_x^\infty F^c(y + x) dy$ .

The current and remaining life have the same limiting distribution. In particular,

$$\lim_{t\to\infty} \mathbb{P}(C_t \le x) = \lim_{t\to\infty} \mathbb{P}(R_t \le x) = \frac{1}{\mu} \int_0^x F^c(y) \, dy, \quad x \in [0,\infty)$$
(15.3.21)

Proof

By the previous two theorems, the limiting right distribution functions of  $R_t$  and  $C_t$  are the same. The ordinary (left) limiting distribution function is

$$1 - \frac{1}{\mu} \int_{x}^{\infty} F^{c}(y) \, dy = \frac{1}{\mu} \left( \mu - \int_{x}^{\infty} F^{c}(y) \, dy \right) \tag{15.3.22}$$

But recall that  $\mu = \int_0^\infty F^c(y) \, dy$  so the result follows since  $\int_0^\infty F^c(y) \, dy - \int_x^\infty F^c(y) \, dy = \int_0^x F^c(y) \, dy$ 

The fact that the current and remaining age processes have the same limiting distribution may seem surprising at first, but there is a simple intuitive explanation. After a long period of time, the renewal process looks just about the same backward in time as forward in time. But reversing the direction of time reverses the rolls of current and remaining age.

## **Examples and Special Cases**

#### The Poisson Process

Recall that the Poisson process, the most important of all renewal processes, has interarrival times that are exponentially distributed with rate parameter r > 0. Thus, the interarrival distribution function is  $F(x) = 1 - e^{-rx}$  for  $x \ge 0$  and the mean interarrival time is  $\mu = 1/r$ .

Verify each of the following directly:

- 1. The law of large numbers for the counting process.
- 2. The central limit theorem for the counting process.
- 3. The elementary renewal theorem.
- 4. The renewal theorem.

## **Bernoulli Trials**

Suppose that  $X = (X_1, X_2, ...)$  is a sequence of Bernoulli trials with success parameter  $p \in (0, 1)$ . Recall that X is a sequence of independent, identically distributed indicator variables with  $p = \mathbb{P}(X = 1)$ . We have studied a number of random processes

## derived from X:

Random processes associated with Bernoulli trials.

- 1.  $\mathbf{Y} = (Y_0, Y_1, ...)$  where  $Y_n$  the number of successes in the first n trials. The sequence  $\mathbf{Y}$  is the partial sum process associated with  $\mathbf{X}$ . The variable  $Y_n$  has the binomial distribution with parameters n and p.
- 2.  $U = (U_1, U_2, ...)$  where  $U_n$  the number of trials needed to go from success number n 1 to success number n. These are independent variables, each having the geometric distribution on  $\mathbb{N}_+$  with parameter p.
- 3.  $V = (V_0, V_1, ...)$  where  $V_n$  is the trial number of success n. The sequence V is the partial sum process associated with U. The variable  $V_n$  has the negative binomial distribution with parameters n and p.

Consider the renewal process with interarrival sequence U. Thus,  $\mu = 1/p$  is the mean interarrival time, and Y is the counting process. Verify each of the following directly:

- 1. The law of large numbers for the counting process.
- 2. The central limit theorem for the counting process.
- 3. The elementary renewal theorem.

Consider the renewal process with interarrival sequence X. Thus, the mean interarrival time is  $\mu = p$  and the number of arrivals in the interval [0, n] is  $V_{n+1} - 1$  for  $n \in \mathbb{N}$ . Verify each of the following directly:

- 1. The law of large numbers for the counting process.
- 2. The central limit theorem for the counting process.
- 3. The elementary renewal theorem.

## 15.4: Delayed Renewal Processes

## **Basic Theory**

#### Preliminaries

A *delayed renewal process* is just like an ordinary renewal process, except that the first arrival time is allowed to have a different distribution than the other interarrival times. Delayed renewal processes arise naturally in applications and are also found embedded in other random processes. For example, in a Markov chain (which we study in the next chapter), visits to a fixed state, *starting in that state* form the random times of an ordinary renewal process. But visits to a fixed state, *starting in another state* form a delayed renewal process.

Suppose that  $X = (X_1, X_2, ...)$  is a sequence of independent variables taking values in  $[0, \infty)$ , with  $(X_2, X_3, ...)$  identically distributed. Suppose also that  $\mathbb{P}(X_i > 0) > 0$  for  $i \in \mathbb{N}_+$ . The stochastic process with X as the sequence of interarrival times is a *delayed renewal process*.

As before, the actual arrival times are the partial sums of X. Thus let

$$T_n = \sum_{i=1}^n X_i$$
 (15.4.1)

so that  $T_0 = 0$  and  $T_n$  is the time of the *n*th arrival for  $n \in \{1, 2, ...\}$ . Also as before,  $N_t$  is the number of arrivals in [0, t] (not counting  $T_0$ ):

$$N_t = \sum_{n=1}^{\infty} \mathbf{1}(T_n \le t) = \max\{n \in \mathbb{N} : T_n \le t\}$$
 (15.4.2)

If we restart the clock at time  $T_1 = X_1$ , we have an ordinary renewal process with interarrival sequence  $(X_2, X_3, ...)$ . We use some of the standard notation developed in the Introduction for this renewal process. In particular, F denotes the common distribution function and  $\mu$  the common mean of  $X_i$  for  $i \in \{2, 3, ...\}$ . Similarly  $F_n = F^{*n}$  denotes the distribution function of the sum of n independent variables with distribution function F, and M denotes the renewal function:

$$M(t) = \sum_{n=1}^{\infty} F_n(t), \quad t \in [0,\infty)$$
 (15.4.3)

On the other hand, we will let G denote the distribution function of  $X_1$  (the special interarrival time, different from the rest), and we will let  $G_n$  denote the distribution function of  $T_n$  for  $n \in \mathbb{N}_+$ . As usual,  $F^c = 1 - F$  and  $G^c = 1 - G$  are the corresponding right-tail distribution functions.

$$G_n=G*F_{n-1}=F_{n-1}*G \ \ ext{for} \ n\in\mathbb{N}_+\,.$$

Proof

The follows from the fact that  $T_n$  is the sum of n independent random variables; the first has distribution function G and the remaining n-1 have distribution function F.

Finally, we will let *U* denote the renewal function for the delayed renewal process. Thus,  $U(t) = \mathbb{E}(N_t)$  is the expected number of arrivals in [0, t] for  $t \in [0, \infty)$ .

The delayed renewal function satisfies

$$U(t) = \sum_{n=1}^{\infty} G_n(t), \quad t \in [0,\infty)$$
 (15.4.4)

Proof

The proof is just as before.

 $\odot$ 

$$U(t) = \mathbb{E}(N_t) = \mathbb{E}\left(\sum_{n=1}^{\infty} \mathbf{1}(T_n \le t)\right) = \sum_{n=1}^{\infty} \mathbb{P}(T_n \le t) = \sum_{n=1}^{\infty} G_n(t)$$
(15.4.5)

The delayed renewal function U satisfies the equation  $U=G+M\ast G\,$  ; that is,

$$U(t) = G(t) + \int_0^t M(t-s) \, dG(s), \quad t \in [0,\infty)$$
(15.4.6)

Proof

The proof follows from conditioning on the time of the first arrival  $T_1 = X_1$ . Note first that  $\mathbb{E}(N_t \mid X_1 = s) = 0$  if s > t and  $\mathbb{E}(N_t \mid X_1 = s) = 1 + M(t - s)$  if  $0 \le s \le t$ . Hence

$$U(t) = \int_0^\infty \mathbb{E}(N_t \mid X_1 = s) \, dG(s) = \int_0^t [1 + M(t - s)] \, dG(s) = G(t) + \int_0^t M(t - s) \, dG(s) \tag{15.4.7}$$

The delayed renewal function U satisfies the renewal equation U = G + U \* F; that is,

$$U(t) = G(t) + \int_0^t U(t-s) \, dF(s), \quad t \in [0,\infty) \tag{15.4.8}$$

Proof

Note that

$$U = \sum_{n=1}^{\infty} G_n = G + \sum_{n=2}^{\infty} G_n = G + \sum_{n=2}^{\infty} (G_{n-1} * F) = G + \left(\sum_{n=1}^{\infty} G_n\right) * F = G + U * F$$
(15.4.9)

#### Asymptotic Behavior

In a delayed renewal process only the first arrival time is changed. Thus, it's not surprising that the asymptotic behavior of a delayed renewal process is the same as the asymptotic behavior of the corresponding regular renewal process. Our first result is the *strong law of large numbers* for the delayed renewal process.

 $N_t/t 
ightarrow 1/\mu$  as  $t
ightarrow\infty$  with probability 1.

Proof

We will show that  $T_n/n \to \mu$  as  $n \to \infty$  with probability 1. Then, the proof is exactly like the proof of the law of large numbers for a regular renewal process. For  $n \in \{2, 3, ...\}$ ,

$$\frac{T_n}{n} = \frac{X_1}{n} + \frac{n-1}{n} \frac{1}{n-1} \sum_{i=2}^n X_i$$
(15.4.10)

But  $\frac{X_1}{n} \to 0$  as  $n \to \infty$  with probability 1; of course  $\frac{n}{n-1} \to 1$  as  $n \to \infty$ ; and  $\frac{1}{n-1} \sum_{i=2}^n X_i \to \mu$  as  $n \to \infty$  with probability 1 by the ordinary strong law of large numbers.

Our next result is the *elementary renewal theorem* for the delayed renewal process.

$$U(t)/t o 1/\mu$$
 as  $t o \infty$  .

Next we have the renewal theorem for the delayed renwal process, also known as Blackwell's theorem, named for David Blackwell.

For h>0 ,  $U(t,t+h]=U(t+h)-U(t) o h/\mu \quad ext{as } t o \infty ext{ in each of the following cases:}$ 

1. *F* is non-arithmetic

2. *F* is arithmetic with span  $d \in (0, \infty)$ , and *h* is a multiple of *d*.

Finally we have the key renewal theorem for the delayed renewal process.

Suppose that the renewal process is non-arithmetic and that  $g: [0, \infty) \to [0, \infty)$  is directly Riemann integrable. Then

$$(g * U)(t) = \int_0^t g(t - s) \, dU(s) \to \frac{1}{\mu} \int_0^\infty g(x) \, dx \text{ as } t \to \infty$$
(15.4.11)

#### Stationary Point Processes

Recall that a *point process* is a stochastic process that models a discrete set of random points in a measure space  $(S, \mathscr{S}, \lambda)$ . Often, of course,  $S \subseteq \mathbb{R}^n$  for some  $n \in \mathbb{N}_+$  and  $\lambda$  is the corresponding *n*-dimensional Lebesgue measure. The special cases  $S = \mathbb{N}$  with counting measure and  $S = [0, \infty)$  with length measure are of particular interest, in part because renewal and delayed renewal processes give rise to point processes in these spaces.

For a general point process on S, we use our standard notation and denote the number of random points  $A \in \mathscr{S}$  by N(A). There are a couple of natural properties that a point process may have. In particular, the process is said to be *stationary* if  $\lambda(A) = \lambda(B)$  implies that N(A) and N(B) have the same distribution for A,  $B \in \mathscr{S}$ . In  $[0, \infty)$  the term *stationary increments* is often used, because the stationarity property means that for s,  $t \in [0, \infty)$ , the distribution of  $N(s, s+t] = N_{s+t} - N_s$  depends only on t.

Consider now a regular renewal process. We showed earlier that the asymptotic distributions of the current life and remaining life are the same. Intuitively, after a very long period of time, the renewal process looks pretty much the same forward in time or backward in time. This suggests that if we make the renewal process into a delayed renewal process by giving the first arrival time this asymptotic distribution, then the resulting point process will be stationary. This is indeed the case. Consider the setting and notation of the preliminary subsection above.

For the delayed renewal process, the point process N is stationary if and only if the initial arrival time has distribution function

$$G(t) = \frac{1}{\mu} \int_0^t F^c(s) \, ds, \quad t \in [0, \infty) \tag{15.4.12}$$

in which case the renewal function is  $U(t) = t/\mu$  for  $t \in [0, \infty)$ .

Proof

Suppose first that N has stationary increments. In particular, this means that the arrival times have continuous distributions. For  $s, t \in [0, \infty)$ ,

$$U(s+t) = \mathbb{E}(N_{s+t}) = \mathbb{E}[(N_{s+t} - N_t) + N_t] = \mathbb{E}(N_{s+t} - N_t) + \mathbb{E}(N_t) = U(s) + U(t)$$
(15.4.13)

A theorem from analysis states that the only increasing solutions to such a functional equation are linear functions, and hence U(t) = ct for some positive constant c. Substituting  $m_d$  into the renewal equation above gives

$$ct = G(t) + \int_0^t c(t-s) \, dF(s) = G(t) + ct \, F(t) - \int_0^t cs \, dF(s) \tag{15.4.14}$$

Integrating by parts in the last integral and simplifying gives

$$G(t) = c \int_0^t F^c(s) \, ds \tag{15.4.15}$$

Finally, if we let  $t \to \infty$ , the left side converges to 1 and the right side to  $c\mu$ , so  $c = 1/\mu$ . Thus G has the form given in the statement of the theorem and  $U(t) = t/\mu$  for  $t \in [0, \infty)$ .

Conversely, suppose that *G* has the form given in the theorem. Note that this is a continuous distribution with density function  $t \mapsto F^c(t)/\mu$ . Substituting into the renewal equation above, it follows that the renewal density U' satisfies

$$U' = \frac{1}{\mu}F^c + \frac{1}{\mu}F^c * \sum_{n=1}^{\infty}F_n = \frac{1}{\mu}$$
(15.4.16)

Hence  $U(t) = t/\mu$  for  $t \ge 0$ . Next, the process N has stationary increments if and only if the remaining life  $R_t$  at time t has distribution function G for each t. Arguing just as in Section 2, we have

$$\mathbb{P}(R_t > y) = G^c(t+y) + \int_0^t F^c(t+y-s) \, dm_d(s), \quad y \ge 0 \tag{15.4.17}$$

But  $G^c(t+y) = \frac{1}{\mu} \int_{t+y}^{\infty} F^c(u) du$  and  $dU(s) = \frac{1}{\mu} ds$ , so substituting into the last displayed equation and using a simple substitution in the integral gives

$$\mathbb{P}(R_t > y) = \frac{1}{\mu} \int_{t+y}^{\infty} F^c(u) \, du + \frac{1}{\mu} \int_{y}^{t+y} F^c(u) \, du = \frac{1}{\mu} \int_{y}^{\infty} F^c(u) \, du \tag{15.4.18}$$

## **Examples and Applications**

#### Patterns in Multinomial Trials

Suppose that  $L = (L_1, L_2, ...)$  is a sequence of independent, identically distributed random variables taking values in a finite set S, so that L is a sequence of multinomial trials. Let f denote the common probability density function so that for a generic trial variable L, we have  $f(a) = \mathbb{P}(L = a)$  for  $a \in S$ . We assume that all outcomes in S are actually possible, so f(a) > 0 for  $a \in S$ .

In this section, we interpret *S* as an *alphabet*, and we write the sequence of variables in concatenation form,  $L = L_1 L_2 \cdots$  rather than standard sequence form. Thus the sequence is an infinite string of letters from our alphabet *S*. We are interested in the repeated occurrence of a particular finite substring of letters (that is, a "word" or "pattern") in the infinite sequence.

So, fix a word  $\boldsymbol{a}$  (again, a finite string of elements of S), and consider the successive random trial numbers  $(T_1, T_2, ...)$  where the word  $\boldsymbol{a}$  is completed in  $\boldsymbol{L}$ . Since the sequence  $\boldsymbol{L}$  is independent and identically distributed, it seems reasonable that these variables are the arrival times of a renewal process. However there is a slight complication. An example may help.

Suppose that $m L$ is a sequence of Bernoulli trials (so $S=\{0,1\}$ ). Suppose that the outcome of $m L$ is	
$10110010101000110\cdots$	(15.4.19)

- 1. For the word  $oldsymbol{a}=001$  note that  $T_1=7$  ,  $T_2=15$  ,  $T_3=22$
- 2. For the word  $oldsymbol{b}=010$ , note that  $T_1=8$  ,  $T_2=10$  ,  $T_3=12$  ,  $T_4=19$

In this example, you probably noted an important difference between the two words. For b, a *suffix* of the word (a proper substring at the end) is also a *prefix* of the word (a proper substring at the beginning. Word a does not have this property. So, once we "arrive" at b, there are ways to get to b again (taking advantage of the suffix-prefix) that do not exist starting from the beginning of the trials. On the other hand, once we arrive at a, arriving at a again is just like with a new sequence of trials. Thus we are lead to the following definition.

Suppose that *a* is a finite word from the alphabet *S*. If no proper suffix of *a* is also a prefix, then *a* is *simple*. Otherwise, *a* is *compound*.

Returning to the general setting, let  $T_0 = 0$  and then let  $X_n = T_n - T_{n-1}$  for  $n \in \mathbb{N}_+$ . For  $k \in \mathbb{N}$ , let  $N_k = \sum_{n=1}^{\infty} \mathbf{1}(T_n \leq k)$ . For occurrences of the word  $\mathbf{a}$ ,  $\mathbf{X} = (X_1, X_2, ...)$  is the sequence of interarrival times,  $\mathbf{T} = (T_0, T_1, ...)$  is the sequence of arrival times, and  $\mathbf{N} = \{N_k : k \in \mathbb{N}\}$  is the counting process. If  $\mathbf{a}$  is simple, these form an ordinary renewal process. If  $\mathbf{a}$  is compound, they form a delayed renewal process, since  $X_1$  will have a different distribution than  $(X_2, X_3, ...)$ . Since the structure of a delayed renewal process subsumes that of an ordinary renewal process, we will work with the notation above for the delayed process. In particular, let U denote the renewal function. Everything in this paragraph depends on the word  $\mathbf{a}$  of course, but we have suppressed this in the notation.

Suppose  $a = a_1 a_2 \cdots a_k$ , where  $a_i \in S$  for each  $i \in \{1, 2, \dots, k\}$ , so that a is a word of length k. Note that  $X_1$  takes values in  $\{k, k+1, \dots\}$ . If a is simple, this applies to the other interarrival times as well. If a is compound, the situation is more complicated  $X_2, X_3, \dots$  will have some minimum value j < k, but the possible values are positive integers, of course, and include  $\{k+1, k+2, \dots\}$ . In any case, the renewal process is arithmetic with span 1. Expanding the definition of the probability density function f, let

$$f(a) = \prod_{i=1}^{k} f(a_i)$$
(15.4.20)

so that f(a) is the probability of forming a with k consecutive trials. Let  $\mu(a)$  denote the common mean of  $X_n$  for  $n \in \{2, 3, ...\}$ , so  $\mu(a)$  is the mean number of trials between occurrences of a. Let  $\nu(a) = \mathbb{E}(X_1)$ , so that  $\nu(a)$  is the mean time

number of trials until a occurs for the first time. Our first result is an elegant connection between  $\mu(a)$  and f(a), which has a wonderfully simple proof from renewal theory.

If  $\boldsymbol{a}$  is a word in S then

$$\mu(\boldsymbol{a}) = \frac{1}{f(\boldsymbol{a})} \tag{15.4.21}$$

Proof

Suppose that a has length k, and consider the discrete interval  $(n, n+k] = \{n+1, n+2, ..., n+k\}$ . By the renewal theorem,  $U(n, n+k] \rightarrow 1/\mu(a)$  as  $n \rightarrow \infty$ . But N(n, n+k], the number of times that a occurs in the interval, is either 1 or 0. Hence U(n, n+k] = f(a) for any n.

Our next goal is to compute  $\nu(a)$  in the case that a is a compound word.

Suppose that a is a compound word, and that b is the largest word that is a proper suffix and prefix of a. Then

$$\nu(a) = \nu(b) + \mu(a) = \nu(b) + \frac{1}{f(a)}$$
(15.4.22)

Proof

Since **b** is the largest prefix-suffix, the expected number of trials to go from **b** to **a** is the same as the expected number of trials to go from **a** to **a**, namely  $\mu(a)$ . (Note that the paths from **b** to **a** are the same as the paths from **a** to **a**.) But to form the word **a** initially, the word **b** must be formed first, so this result follows from the additivity of expected value and the previous result.

By repeated use of the last result, we can compute the expected number of trials needed to form any compound word.

Consider Bernoulli trials with success probability  $p \in (0, 1)$ , and let q = 1 - p. For each of the following strings, find the expected number of trials between occurrences and the expected number of trials to the first occurrence.

1. 
$$a = 001$$
  
2.  $b = 010$   
3.  $c = 1011011$   
4.  $d = 11 \cdots 1$  (k times)  
Answer  
1.  $\mu(a) = \nu(a) = \frac{1}{pq^2}$   
2.  $\mu(b) = \frac{1}{pq^2}$ ,  $\nu(b) = \frac{1}{q} + \frac{1}{pq^2}$   
3.  $\mu(c) = \frac{1}{p^5q^2}$ ,  $\nu(c) = \frac{1}{p} + \frac{1}{p^3q} + \frac{1}{p^4}$   
4.  $\mu(d) = \frac{1}{p^k} \nu(d) = \sum_{i=1}^k \frac{1}{p^i}$ 

Recall that an *ace-six flat die* is a six-sided die for which faces 1 and 6 have probability  $\frac{1}{4}$  each while faces 2, 3, 4, and 5 have probability  $\frac{1}{8}$  each. Ace-six flat dice are sometimes used by gamblers to cheat.

Suppose that an ace-six flat die is thrown repeatedly. Find the expected number of throws until the pattern 6165616 first occurs.

Solution

From our main theorem,

$$\begin{split} \nu(6165616) &= \frac{1}{f(6165616)} + \nu(616) = \frac{1}{f(6165616)} + \frac{1}{f(616)} + \nu(6) \\ &= \frac{1}{f(6165616)} + \frac{1}{f(616)} + \frac{1}{f(6)} = \frac{1}{(1/4)^6 (1/8)} + \frac{1}{(1/4)^3} + \frac{1}{1/4} = 32\,836 \end{split}$$

Suppose that a monkey types randomly on a keyboard that has the 26 lower-case letter keys and the space key (so 27 keys). Find the expected number of keystrokes until the monkey produces each of the following phrases:

1. it was the best of times 2. to be or not to be Proof 1.  $27^{24} \approx 2.258 \times 10^{34}$ 2.  $27^5 + 27^{18} \approx 5.815 \times 10^{25}$

# 15.5: Alternating Renewal Processes

## Basic Theory

## Preliminaries

An *alternating renewal process* models a system that, over time, alternates between two states, which we denote by 1 and 0 (so the system starts in state 1). Generically, we can imagine a device that, over time, alternates between *on* and *off* states. Specializing further, suppose that a device operates until it fails, and then is replaced with an identical device, which in turn operates until failure and is replaced, and so forth. In this setting, the times that the device is functioning correspond to the *on* state, while the replacement times correspond to the *off* state. (The device might actually be *repaired* rather than *replaced*, as long as the repair returns the device to pristine, new condition.) The basic assumption is that the pairs of random times successively spent in the two states form an independent, identically distributed sequence. Clearly the model of a system alternating between two states is basic and important, but moreover, such alternating processes are often found embedded in other stochastic processes.

Let's set up the mathematical notation. Let  $U = (U_1, U_2, ...)$  denote the successive lengths of time that the system is in state 1, and let  $V = (V_1, V_2, ...)$  the successive lengths of time that the system is in state 0. So to be clear, the system starts in state 1 and remains in that state for a period of time  $U_1$ , then goes to state 0 and stays in this state for a period of time  $V_1$ , then back to state 1 for a period of time  $U_2$ , and so forth. Our basic assumption is that  $W = ((U_1, V_1), (U_2, V_2), ...)$  is an independent, identically distributed sequence. It follows that U and V each are independent, identically distributed sequences, but U and V might well be dependent. In fact,  $V_n$  might be a function of  $U_n$  for  $n \in \mathbb{N}_+$ . Let  $\mu = \mathbb{E}(U)$  denote the mean of a generic time period U in state 1 and let  $\nu = \mathbb{E}(V)$  denote the mean of a generic time period U in state 1, and let  $u = \mathbb{E}(V)$  denote the mean of a generic time period U in state 1, and as usual, let  $G^c = 1 - G$  denote the right distribution function (or reliability function) of U.

Clearly it's natural to consider returns to state 1 as the arrivals in a renewal process. Thus, let  $X_n = U_n + V_n$  for  $n \in \mathbb{N}_+$  and consider the renewal process with interarrival times  $\mathbf{X} = (X_1, X_2, \ldots)$ . Clearly this makes sense, since  $\mathbf{X}$  is an independent, identically distributed sequence of nonnegative variables. For the most part, we will use our usual notation for a renewal process, so the common distribution function of  $X_n = U_n + V_n$  is denoted by F, the arrival time process is  $\mathbf{T} = (T_0, T_1, \ldots)$ , the counting process is  $\{N_t : t \in [0, \infty)\}$ , and the renewal function is M. But note that the mean interarrival time is now  $\mu + \nu$ .

The renwal process associated with  $W = ((U_1, V_1), (U_2, V_2), ...)$  as constructed above is known as an *alternating renewal* process.

#### The State Process

Our interest is the state  $I_t$  of the system at time  $t \in [0, \infty)$ , so  $I = \{I_t : t \in [0, \infty)\}$  is a stochastic process with state space  $\{0, 1\}$ . Clearly the stochastic processes W and I are equivalent in the sense that we can recover one from the other. Let  $p(t) = \mathbb{P}(I_t = 1)$ , the probability that the device is on at time  $t \in [0, \infty)$ . Our first main result is a renewal equation for the function p.

The function p satisfies the renewal equation  $p = G^c + p \ast F$  and hence  $p = G^c + G^c \ast M$  .

Proof

By now, the approach should be clear—we're going to condition on the first arrival  $X_1$ :

$$\mathbb{P}(I_t = 1) = \mathbb{P}(I_t = 1, X_1 > t) + \mathbb{P}(I_t = 1, X_1 \le t) = \mathbb{P}(I_t = 1, X_1 > t) + \int_0^t \mathbb{P}(I_t = 1 \mid X_1 = s) \, dF(s) \quad (15.5.1)$$

But  $\{I_t = 1, X_1 > t\} = \{U_1 > t\}$  so  $\mathbb{P}(I_t = 1, X_1 > t) = \mathbb{P}(U_1 > t) = G^c(t)$ . By the fundamental renewal property (the process restarts, independently of the past, at each arrival)  $\mathbb{P}(I_t = 1 | X_1 = s) = p(t - s)$  for  $s \le t$ . Hence we have

$$p(t) = G^c(t) + \int_0^t p(t-s) \, dF(s), \quad t \in [0,\infty)$$
 (15.5.2)

or equivalently,  $p = G^c + p * F$ . By the fundamental theorem on renewal equations, the solution is  $p = G^c + G^c * M$ , so  $p(t) = G^c(t) + \int_0^t G^c(t-s) \, dM(s), \quad t \in [0,\infty)$ 

We can now apply the key renewal theorem to get the asymptotic behavior of p.

If the renewal process is non-arithmetic, then

$$p(t) \to \frac{\mu}{\mu + \nu} \text{ as } t \to \infty$$
 (15.5.3)

Proof

From the result above,  $p = G^c + G^c * m$ . First,  $G^c(t) \to 0$  as  $t \to \infty$  as a basic property of the right distribution function. Next, by the key renewal theorem,

$$(G^c * M)(t) 
ightarrow rac{1}{\mu + 
u} \int_0^\infty G^c(s) \, ds ext{ as } t 
ightarrow \infty ext{ (15.5.4)}$$

But by another basic property of the right distribution function,  $\int_0^\infty G^c(s)\,ds=\mu$  .

Thus, the limiting probability that the system is on is simply the ratio of the mean of an *on* period to the mean of an *on-off* period. It follows, of course, that

$$\mathbb{P}(I_t=0)=1-p(t)
ightarrow rac{
u}{\mu+
u} ext{ as } t
ightarrow \infty$$
 $(15.5.5)$ 

so in particular, the fact that the system starts in the on state makes no difference in the limit. We will return to the asymptotic behavior of the alternating renewal process in the next section on renewal reward processes.

## **Applications and Special Cases**

With a clever definition of *on* and *off*, many stochastic processes can be turned into alternating renewal processes, leading in turn to interesting limits, via the basic limit theorem above.

#### Age Processes

The last remark applies in particular to the age processes of a standard renewal process. So, suppose that we have a renewal process with interarrival sequence  $\boldsymbol{X}$ , arrival sequence  $\boldsymbol{T}$ , and counting process  $\boldsymbol{N}$ . As usual, let  $\mu$  denote the mean and F the probability distribution function of an interarrival time, and let  $F^c = 1 - F$  denote the right distribution function (or reliability function).

For  $t \in [0, \infty)$ , recall that the *current life*, *remaining life* and *total life* at time t are

$$C_t = t - T_{N_t}, \quad R_t = T_{N_t+1} - t, \quad L_t = C_t + R_t = T_{N_t+1} - T_{N_t} = X_{N_t+1}$$
(15.5.6)

respectively. In the usual terminology of reliability,  $C_t$  is the age of the device in service at time t,  $R_t$  is the time remaining until this device fails, and  $L_t$  is total life of the device. We will use limit theorem above to derive the limiting distributions these age processes. The limiting distributions were obtained earlier, in the section on renewal limit theorems, by a direct application of the key renewal theorem. So the results are not new, but the method of proof is interesting.

If the renewal process is non-arithmetic then

$$\lim_{t\to\infty}\mathbb{P}(C_t\leq x)=\lim_{t\to\infty}\mathbb{P}(R_t\leq x)=\frac{1}{\mu}\int_0^xF^c(y)\,dy,\quad x\in[0,\infty) \tag{15.5.7}$$

Proof

Fix  $x \in [0, \infty)$ . For the current life limit, define the *on* period corresponding to the interarrival time  $X_n$  to be  $U_n = \min\{X_n, x\}$  for  $n \in \mathbb{N}_+$ , so that the *off* period is  $V_n = X_n - \min\{X_n, x\}$ . Note that the system is on at time  $t \in [0, \infty)$  if and only if  $C_t \leq x$ , and hence  $p(t) = \mathbb{P}(C_t \leq x)$ . It follows from the limit theorem above that

$$\mathbb{P}(C_t \le x) o rac{\mathbb{E}[\min\{X, x\}]}{\mu} ext{ as } t o \infty$$
(15.5.8)

where X is a generic interarrival time. But

$$G^{c}(y) = \mathbb{P}[\min\{X, x\} > y] = \mathbb{P}(X > y)\mathbf{1}(x > y) = F^{c}(y)\mathbf{1}(x > y), \quad y \in [0, \infty)$$
 (15.5.9)

Hence

$$\mathbb{E}[\min(X,x)] = \int_0^\infty G^c(y) \, dy = \int_0^x F^c(y) \, dy \tag{15.5.10}$$

For the remaining life limit we reverse the on-off periods. Thus, define the *on* period corresponding to the interarrival time  $X_n$  to be  $U_n = X_n - \min\{X_n, x\}$  for  $n \in \mathbb{N}_+$ , so that the *off* period is  $V_n = \min\{X_n, x\}$ . Note that the system is off at time t if and only if  $R_t \leq x$ , and hence  $1 - p(t) = \mathbb{P}(R_t \leq x)$ . From the limit theorem above,

$$\mathbb{P}(R_t \le x) o rac{\mathbb{E}[\min\{X, x\}]}{\mu} ext{ as } t o \infty$$
 (15.5.11)

As we have noted before, the fact that the limiting distributions are the same is not surprising after a little thought. After a long time, the renewal process looks the same forward and backward in time, and reversing the arrow of time reverses the roles of current and remaining time.

If the renewal process is non-arithmetic then

$$\lim_{t o\infty}\mathbb{P}(L_t\leq x)=rac{1}{\mu}\int_0^x y\,dF(y),\quad x\in[0,\infty)$$
(15.5.12)

Proof

Fix  $x \in [0, \infty)$ . For  $n \in \mathbb{N}_+$ , define the *on* period associated with interarrival time  $X_n$  by  $U_n = X_n \mathbf{1}(X_n > x)$ . Of course, the *off* period corresponding to  $X_n$  is  $V_n = X_n - U_n$ . Thus, each renewal period is either totally on or totally off, depending on whether or not the interarrival time is greater than x. Note that the system is on at time  $t \in [0, \infty)$  if and only if  $L_t > x$ , so from the basic limit theorem above,

$$\mathbb{P}(L_t > x) \to \frac{1}{\mu} \mathbb{E}[X\mathbf{1}(X > x)] \tag{15.5.13}$$

where X is a generic interarrival time. But

$$\mathbb{E}[X\mathbf{1}(X > x)] = \int_x^\infty y \, dF(y) \tag{15.5.14}$$

## 15.6: Renewal Reward Processes

## **Basic Theory**

#### Preliminaries

In a *renewal reward process*, each interarrival time is associated with a random variable that is generically thought of as the *reward* associated with that interarrival time. Our interest is in the process that gives the total reward up to time *t*. So let's set up the usual notation. Suppose that  $\mathbf{X} = (X_1, X_2, ...)$  are the interarrival times of a renewal process, so that  $\mathbf{X}$  is a sequence of independent, identically distributed, nonnegative variables with common distribution function *F* and mean  $\mu$ . As usual, we assume that F(0) < 1 so that the interarrival times are not deterministically 0, and in this section we also assume that  $\mu < \infty$ . Let

$$T_n = \sum_{i=1}^n X_i, \quad n \in \mathbb{N}$$
(15.6.1)

so that  $T_n$  is the time of the *n*th arrival for  $n \in \mathbb{N}_+$  and  $T = (T_0, T_1, \ldots)$  is the arrival time sequence. Finally, Let

$$N_t = \sum_{n=1}^{\infty} \mathbf{1}(T_n \le t), \quad t \in [0, \infty)$$
 (15.6.2)

so that  $N_t$  is the number of arrivals in [0, t] and  $N = \{N_t : t \in [0, \infty)\}$  is the counting process. As usual, let  $M(t) = \mathbb{E}(N_t)$  for  $t \in [0, \infty)$  so that M is the renewal function.

Suppose now that  $Y = (Y_1, Y_2, ...)$  is a sequence of real-valued random variables, where  $Y_n$  is thought of as the reward associated with the interarrival time  $X_n$ . However, the term *reward* should be interpreted generically since  $Y_n$  might actually be a *cost* or some other value associated with the interarrival time, and in any event, may take negative as well as positive values. Our basic assumption is that the interarrival time and reward pairs  $Z = ((X_1, Y_1), (X_2, Y_2), ...)$  form an independent and identically distributed sequence. Recall that this implies that X is an IID sequence, as required by the definition of the renewal process, and that Y is also an IID sequence. But X and Y might well be dependent, and in fact  $Y_n$  might be a function of  $X_n$  for  $n \in \mathbb{N}_+$ . Let  $\nu = \mathbb{E}(Y)$  denote the mean of a generic reward Y, which we assume exists in  $\mathbb{R}$ .

The stochastic process  $oldsymbol{R} = \{R_t : t \in [0,\infty)\}$  defined by

$$R_t = \sum_{i=1}^{N_t} Y_i, \quad t \in [0,\infty)$$
 (15.6.3)

is the *reward renewal process* associated with Z. The function r given by  $r(t) = \mathbb{E}(R_t)$  for  $t \in [0, \infty)$  is the *reward function*.

As promised,  $R_t$  is the total reward up to time  $t \in [0, \infty)$ . Here are some typical examples:

- The arrivals are customers at a store. Each customer spends a random amount of money.
- The arrivals are visits to a website. Each visitor spends a random amount of time at the site.
- The arrivals are failure times of a complex system. Each failure requires a random repair time.
- The arrivals are earthquakes at a particular location. Each earthquake has a random severity, a measure of the energy released.

So  $R_t$  is a random sum of random variables for each  $t \in [0, \infty)$ . In the special case that Y and X independent, the distribution of  $R_t$  is known as a *compound distribution*, based on the distribution of  $N_t$  and the distribution of a generic reward Y. Specializing further, if the renewal process is Poisson and is independent of Y, the process R is a compound Poisson process.

Note that a renewal reward process generalizes an ordinary renewal process. Specifically, if  $Y_n = 1$  for each  $n \in \mathbb{N}_+$ , then  $R_t = N_t$  for  $t \in [0, \infty)$ , so that the reward process simply reduces to the counting process, and then r reduces to the renewal function M.

#### The Renewal Reward Theorem

For  $t \in (0, \infty)$ , the average reward on the interval [0, t] is  $R_t/t$ , and the expected average reward on that interval is r(t)/t. The fundamental theorem on renewal reward processes gives the asymptotic behavior of these averages.

#### The renewal reward theorem

1.  $R_t/t o 
u/\mu$  as  $t o \infty$  with probability 1. 2.  $r(t)/t o 
u/\mu$  as  $t o \infty$ 

Proof

1. Note that

$$\frac{R_t}{t} = \frac{R_t}{N_t} \frac{N_t}{t} \tag{15.6.4}$$

But by the ordinary strong law of large numbers for the IID sequence  $\boldsymbol{Y}$ ,

$$\frac{1}{n}\sum_{i=1}^{n}Y_{i} \to \nu \tag{15.6.5}$$

as  $n \to \infty$  with probability 1. Recal also that  $N_t \to \infty$  as  $t \to \infty$  with probability 1. Hence it follows that

$$\frac{R_t}{N_t} = \frac{1}{N_t} \sum_{i=1}^{N_t} Y_i \to \nu$$
(15.6.6)

as  $t \to \infty$  with probability 1. From the law or large numbers for the renewal process, we know that  $N_t/t \to 1/\mu$  as  $t \to \infty$  with probability 1.

2. Note first that

$$R_t = \sum_{i=1}^{N_t} Y_i = \sum_{i=1}^{N_t+1} Y_i - Y_{N(t)+1}$$
(15.6.7)

Next Recall that  $N_t + 1$  is a stopping time for the sequence of interarrival times X for  $t \in (0, \infty)$ , and hence is also a stopping time for the sequence of interarrival time, reward pairs Z. (If a random time is a stopping time for a filtration, then it's a stopping time for any larger filtration.) By Wald's equation,

$$\mathbb{E}\left(\sum_{i=1}^{N_t+1} Y_i\right) = \nu \mathbb{E}\left(N_t+1\right) = \nu [M(t)+1] = \nu M(t) + \nu$$
(15.6.8)

By the elementary renewal theorem,

$$\frac{\nu M(t) + \nu}{t} = \nu \frac{M(t)}{t} + \frac{\nu}{t} \to \frac{\nu}{\mu} \text{ as } t \to \infty$$
(15.6.9)

Thus returning to the first displayed equation above, it remains to show that

$$rac{\mathbb{E}\left[Y_{N_t+1}
ight]}{t} o 0 ext{ as } t o \infty ext{ (15.6.10)}$$

Let  $u(t) = \mathbb{E}[Y_{N_t+1}]$  for  $t \in [0,\infty)$ . Taking cases for the first arrival time  $X_1$  we have

$$u(t) = \mathbb{E}\left[Y_{N_t+1}\mathbf{1}(X_1 > t)\right] + \mathbb{E}\left[Y_{N_t+1}\mathbf{1}(X_1 \le t)\right]$$
(15.6.11)

But  $X_1 > t$  if and only if  $N_t = 0$  so the first term is  $\mathbb{E}[Y_1 \mathbf{1}(X_1 > t)]$ , which we will note by a(t). We have assumed that the expected reward  $\nu$  exists in  $\mathbb{R}$ . Hence  $|a(t)| \le \mathbb{E}(|Y_1|) < \infty$  so that a is bounded, and  $a(t) \to 0$  as  $t \to \infty$ . For the second term, if the first arrival occurs at time  $s \in [0, t]$ , then the renewal process restarts, independently of the past, so

$$\mathbb{E}\left[Y_{N_t+1} \mathbf{1}(X_1 \le t)
ight] = \int_0^t u(t-s) \, dF(s), \quad t \in [0,\infty)$$
 (15.6.12)

It follows that u satisfies the renewal equation u = a + u \* F. By the fundamental theorem on renewal equations, the solution is u = a + a \* M. Now, fix  $\epsilon > 0$ . There exists  $T \in (0, \infty)$  such that  $|a(t)| < \epsilon$  for t > T. So for t > T,

$$egin{aligned} \left| egin{aligned} rac{u(t)}{t} 
ight| &\leq rac{1}{t} \left[ |a(t)| + \int_0^{t-T} |a(t-s)| \, dM(s) + \int_{t-M}^t |a(t-s)| \, dM(s) 
ight] \ &\leq rac{1}{t} [\epsilon + \epsilon \, M(t-T) + \mathbb{E} \left| Y_1 
ight| \left[ M(t) - M(t-T) 
ight] ] \end{aligned}$$

Using the elementary renewal theorem again, the last expression converges to  $\epsilon/\mu$  as  $t \to \infty$ . Since  $\epsilon > 0$  is arbitrary, it follows that  $u(t)/t \to 0$  as  $t \to \infty$ .

Part (a) generalizes the law of large numbers and part (b) generalizes elementary renewal theorem, for a basic renewal process. Once again, if  $Y_n = 1$  for each n, then (a) becomes  $N_t/t \rightarrow 1/\mu$  as  $t \rightarrow \infty$  and (b) becomes  $M(t)/t \rightarrow 1/\mu$  as  $t \rightarrow \infty$ . It's not surprising then that these two theorems play a fundamental role in the proof of the renewal reward theorem.

#### **General Reward Processes**

The renewal reward process  $\mathbf{R} = \{R_t : t \in [0, \infty)\}$  above is constant, taking the value  $\sum_{i=1}^n Y_i$ , on the renewal interval  $[T_n, T_{n+1})$  for each  $n \in \mathbb{N}$ . Effectively, the rewards are received discretely:  $Y_1$  at time  $T_1$ , an additional  $Y_2$  at time  $T_2$ , and so forth. It's possible to modify the construction so the rewards accrue continuously in time or in a mixed discrete/continuous manner. Here is a simple set of conditions for a general reward process.

Suppose again that  $\mathbf{Z} = ((X_1, Y_1), (X_2, Y_2), ...)$  is the sequence of interarrival times and rewards. A stochastic process  $\mathbf{V} = \{V_t : t \in [0, \infty)\}$  (on our underlying probability space) is a *reward process* associated with  $\mathbf{Z}$  if the following conditions hold:

1.  $V_{T_n} = \sum_{i=1}^n Y_i$  for  $n \in \mathbb{N}$ 2.  $V_t$  is between  $V_{T_n}$  and  $V_{T_{n+1}}$  for  $t \in (T_n, T_{n+1})$  and  $n \in \mathbb{N}$ 

In the continuous case, with nonnegative rewards (the most important case), the reward process will typically have the following form:

Suppose that the rewards are nonnegative and that  $U = \{U_t : t \in [0, \infty)\}$  is a nonnegative stochastic process (on our underlying probability space) with

1.  $t\mapsto U_t$  piecewise continous 2.  $\int_{T_n}^{T_{n+1}} U_t\,dt = Y_{n+1}\,$  for  $n\in\mathbb{N}$ 

Let  $V_t = \int_0^t U_s \, ds \,$  for  $t \in [0,\infty)$ . Then  $oldsymbol{V} = \{V_t : t \in [0,\infty)\}$  is a reward process associated with  $oldsymbol{Z}$ .

Proof

By the additivity of the integral and (b),  $V_{T_n} = \sum_{i=1}^n Y_i$  for  $n \in \mathbb{N}$ . Since U is nonnegative, V is increasing, so  $V_{T_n} \leq V_t \leq V_{T_{n+1}}$  for  $t \in (T_n, T_{n+1})$ 

Thus in this special case, the rewards are being accrued continuously and  $U_t$  is the *rate* at which the reward is being accrued at time *t*. So U plays the role of a reward density process. For a general reward process, the basic renewal reward theorem still holds.

Suppose that  $V = \{V_t : t \in [0, \infty)\}$  is a reward process associated with  $Z = ((X_1, Y_1), (X_2, Y_2), \ldots)$ , and let  $v(t) = \mathbb{E}(V_t)$  for  $t \in [0, \infty)$  be the corresponding reward function.

1.  $V_t/t o 
u/\mu$  as  $t o \infty$  with probability 1. 2.  $v(t)/t o 
u/\mu$  as  $t o \infty$ .

Proof

Suppose first that the reward variables Y are nonnegative. Then

$$\frac{R_t}{t} \le \frac{V_t}{t} \le \frac{R_t}{t} + \frac{Y_{N_t+1}}{t}$$
(15.6.13)

From the proof of the renewal reward theorem above,  $R_t/t \rightarrow \nu/\mu$  as  $t \rightarrow \infty$  with probability 1, and  $Y_{N_t+1}/t \rightarrow 0$  as  $t \rightarrow \infty$  with probability 1. Hence (a) holds. Taking expected values,

$$\frac{r(t)}{t} \le \frac{v(t)}{t} \le \frac{r(t)}{t} + \frac{\mathbb{E}(Y_{N_t+1})}{t}$$
(15.6.14)

But again from the renewal reward theorem above,  $r(t)/t \rightarrow \nu/\mu$  as  $t \rightarrow \infty$  and  $E(Y_{N_t+1})/t \rightarrow 0$  as  $t \rightarrow \infty$ . Hence (b) holds. A similar argument works if the reward variables are negative. If the reward variables take positive and negative values, we split the variables into positive and negative parts in the usual way.

Here is the corollary for a continuous reward process.

Suppose that the rewards are positive, and consider the continuous reward process with density process  $U = \{U_t : t \in [0, \infty)\}$  as above. Let  $u(t) = \mathbb{E}(U_t)$  for  $t \in [0, \infty)$ . Then

 $\begin{array}{l} 1. \ \frac{1}{t} \int_0^t U_s \, ds \to \frac{\nu}{\mu} \ \text{ as } t \to \infty \ \text{with probability 1} \\ 2. \ \frac{1}{t} \int_0^t u(s) \, ds \to \frac{\nu}{\mu} \ \text{ as } t \to \infty \end{array}$ 

## **Special Cases and Applications**

With a clever choice of the "rewards", many interesting renewal processes can be turned into renewal reward processes, leading in turn to interesting limits via the renewal reward theorem.

#### **Alternating Renewal Processes**

Recall that in an alternating renewal process, a system alternates between *on* and *off* states (starting in the *on* state). If we let  $U = (U_1, U_2, ...)$  be the lengths of the successive time periods in which the system is on, and  $V = (V_1, V_2, ...)$  the lengths of the successive time periods in which the system is off, then the basic assumptions are that  $((U_1, V_1), (U_2, V_2), ...)$  is an independent, identically distributed sequence, and that the variables  $X_n = U_n + V_n$  for  $n \in \mathbb{N}_+$  form the interarrival times of a standard renewal process. Let  $\mu = \mathbb{E}(U)$  denote the mean of a time period that the device is on, and  $\nu = \mathbb{E}(V)$  the mean of a time period that the device is off. Recall that  $I_t$  denotes the state (1 or 0) of the system at time  $t \in [0, \infty)$ , so that  $I = \{I_t : t \in [0, \infty)\}$  is the state process. The state probability function p is given by  $p(t) = \mathbb{P}(I_t = 1)$  for  $t \in [0, \infty)$ .

Limits for the alternating renewal process.

1. 
$$\frac{1}{t} \int_0^t I_s \, ds \to \frac{\mu}{\mu + \nu}$$
 as  $t \to \infty$  with probability 1  
2.  $\frac{1}{t} \int_0^t p(s) \, ds \to \frac{\mu}{\mu + \nu}$  as  $t \to \infty$ 

Proof

Consider the renewal reward process where the reward associated with the interarrival time  $X_n$  is  $U_n$ , the *on* period for that renewal period. The rewards  $U_n$  are nonnegative and clearly  $\int_{T_n}^{T_{n+1}} I_s \, ds = U_{n+1}$ . So  $t \mapsto \int_0^t I_s \, ds$  for  $t \in [0, \infty)$  defines a continuous reward process of the form given above. Parts (a) and (b) follow directly from the reward renewal theorem above.

Thus, the asymptotic average time that the device is on, and the asymptotic mean average time that the device is on, are both simply the ratio of the mean of an on period to the mean of an on-off period. In our previous study of alternating renewal processes, the fundamental result was that in the non-arithmetic case,  $p(t) \rightarrow \mu/(\mu + \nu)$  as  $t \rightarrow \infty$ . This result implies part (b) in the theorem above.

#### Age Processes

Renewal reward processes can be used to derive some asymptotic results for the age processes of a standard renewal process So, suppose that we have a renewal process with interarrival sequence X, arrival sequence T, and counting process N. As usual, let  $\mu = \mathbb{E}(X)$  denote the mean of an interarrival time, but now we will also need  $\nu = \mathbb{E}(X^2)$ , the second moment. We assume that both moments are finite.

For  $t \in [0,\infty)$ , recall that the *current life*, *remaining life* and *total life* at time t are

$$A_t = t - T_{N_t}, \quad B_t = T_{N_t+1} - t, \quad L_t = A_t + B_t = T_{N_t+1} - T_{N_t} = X_{N_t+1}$$
(15.6.15)

respectively. In the usual terminology of reliability,  $A_t$  is the age of the device in service at time t,  $B_t$  is the time remaining until this device fails, and  $L_t$  is total life of the device. (To avoid notational clashes, we are using different notation than in past

sections.) Let  $a(t) = \mathbb{E}(A_t)$ ,  $b(t) = \mathbb{E}(B_t)$ , and  $l(t) = \mathbb{E}(L_t)$  for  $t \in [0, \infty)$ , the corresponding mean functions. To derive our asymptotic results, we simply use the current life and the remaining life as reward densities (or rates) in a renewal reward process.

Limits for the current life process.

1.  $\frac{1}{t} \int_0^t A_s \, ds \to \frac{\nu}{2\mu}$  as  $t \to \infty$  with probability 1 2.  $\frac{1}{t} \int_0^t a(s) \, ds \to \frac{\nu}{2\mu}$  as  $t \to \infty$ 

Proof

Consider the renewal reward process where the reward associated with the interarrival time  $X_n$  is  $\frac{1}{2}X_n^2$  for  $n \in \mathbb{N}$ . The process  $t \mapsto \int_0^t A_s \, ds$  for  $t \in [0, \infty)$  is a continuous reward process for this sequence of rewards, as defined above. To see this, note that for  $t \in [T_n, T_{n+1})$ , we have  $A_t = t - T_n$ , so with a change of variables and noting that  $T_{n+1} = T_n + X_{n+1}$  we have

$$\int_{T_n}^{T_{n+1}} A_t \, dt = \int_0^{X_{n+1}} s \, ds = \frac{1}{2} X_{n+1}^2 \tag{15.6.16}$$

The results now follow from the renewal reward theorem above.

Limits for the remaining life process.

 $\begin{array}{l} 1. \ \frac{1}{t} \int_0^t B_s \ ds \to \frac{\nu}{2\mu} \ \text{as} \ t \to \infty \ \text{with probability} \ 1 \\ 2. \ \frac{1}{t} \int_0^t b(s) \ ds \to \frac{\nu}{2\mu} \ \text{as} \ t \to \infty \end{array}$ 

Proof

Consider again the renewal reward process where the reward associated with the interarrival time  $X_n$  is  $\frac{1}{2}X_n^2$  for  $n \in \mathbb{N}$ . The process  $t \mapsto \int_0^t B_s ds$  for  $t \in [0, \infty)$  is a continuous reward process for this sequence of rewards, as defined above. To see this, note that for  $t \in [T_n, T_{n+1})$ , we have  $B_t = T_{n+1} - t$ , so once again with a change of variables and noting that  $T_{n+1} = T_n + X_{n+1}$  we have

$$\int_{T_n}^{T_{n+1}} B_t \, dt = \int_0^{X_{n+1}} s \, ds = \frac{1}{2} X_{n+1}^2 \tag{15.6.17}$$

The results now follow from the renewal reward theorem above.

With a little thought, it's not surprising that the limits for the current life and remaining life processes are the same. After a long period of time, a renewal process looks stochastically the same forward or backward in time. Changing the "arrow of time" reverses the role of the current and remaining life. Asymptotic results for the total life process now follow trivially from the results for the current and remaining life processes.

Limits for the total life process

 $\begin{array}{l} 1. \ \frac{1}{t} \int_0^t L_s \ ds \to \frac{\nu}{\mu} \ \text{ as } t \to \infty \ \text{with probability 1} \\ 2. \ \frac{1}{t} \int_0^t l(s) \ ds = \frac{\nu}{\mu} \ \text{ as } t \to \infty \end{array}$ 

## **Replacement Models**

Consider again a standard renewal process as defined in the Introduction, with interarrival sequence  $X = (X_1, X_2, ...)$ , arrival sequence  $T = (T_0, T_1, ...)$ , and counting process  $N = \{N_t : t \in [0, \infty)\}$ . One of the most basic applications is to reliability, where a device operates for a random lifetime, fails, and then is replaced by a new device, and the process continues. In this model,  $X_n$  is the lifetime and  $T_n$  the failure time of the *n*th device in service, for  $n \in \mathbb{N}_+$ , while  $N_t$  is the number of failures in [0, t] for  $t \in [0, \infty)$ . As usual, F denotes the distribution function of a generic lifetime X, and  $F^c = 1 - F$  the corresponding right distribution function (reliability function). Sometimes, the device is actually a *system* with a number of critical components—the failure of any of the critical components causes the system to fail.

*Replacement models* are variations on the basic model in which the device is replaced (or the critical components replaced) at times other than failure. Often the cost a of a *planned replacement* is less than the cost b of an *emergency replacement* (at failure), so

replacement models can make economic sense. We will consider the the most common model.

In the *age replacement model*, the device is replaced either when it fails or when it reaches a specified age  $s \in (0, \infty)$ . This model gives rise to a new renewal process with interarrival sequence  $U = (U_1, U_2, ...)$  where  $U_n = \min\{X_n, s\}$  for  $n \in \mathbb{N}_+$ . If  $a, b \in (0, \infty)$  are the costs of planned and unplanned replacements, respectively, then the cost associated with the renewal period  $U_n$  is

$$Y_n = a\mathbf{1}(U_n = s) + b\mathbf{1}(U_n < s) = a\mathbf{1}(X_n \ge s) + b\mathbf{1}(X_n < s)$$
(15.6.18)

Clearly  $((U_1, Y_1), (U_2, Y_2), ...)$  satisfies the assumptions of a renewal reward process given above. The model makes mathematical sense for any  $a, b \in (0, \infty)$  but if  $a \ge b$ , so that the planned cost of replacement is at least as large as the unplanned cost of replacement, then  $Y_n \ge b$  for  $n \in \mathbb{N}_+$ , so the model makes no financial sense. Thus we assume that a < b.

In the age replacement model, with planned replacement at age  $s \in (0, \infty)$ ,

1. The expected cost of a renewal period is  $\mathbb{E}(Y) = aF^{c}(s) + bF(s)$ .

2. The expected length of a renewal period is  $\mathbb{E}(U) = \int_0^s F^c(x) \, dx$ 

The limiting expected cost per unit time is

$$C(s) = \frac{aF^{c}(s) + bF(s)}{\int_{0}^{s} F^{c}(x) dx}$$
(15.6.19)

Proof

Parts (a) and (b) follow from the definition of the reward Y and the renewal period U, and then the formula for C(s) follows from the reward renewal theorem above

So naturally, given the costs a and b, and the lifetime distribution function F, the goal is be to find the value of s that minimizes C(s); this value of s is the *optimal replacement time*. Of course, the optimal time may not exist.

Properties of C

$$1.\ C(s) o \infty ext{ as } s \downarrow 0$$
  
 $2.\ C(s) o \mu/b ext{ as } s \uparrow \infty$ 

Proof

1. Recall that  $F^c(0) > 0$  and  $\int_0^s F^c(x) dx \to 0$  as  $s \downarrow 0$ 2. As  $s \to \infty$  note that  $F^c(s) \to 0$ ,  $F(s) \to 1$  and  $\int_0^s F^c(x) dx \to \int_0^\infty F^c(x) dx = \mu$ 

As  $s \to \infty$ , the age replacement model becomes the standard (unplanned) model with limiting expected average cost  $b/\mu$ .

Suppose that the lifetime of the device (in appropriate units) has the standard exponential distribution. Find C(s) and solve the optimal age replacement problem.

Answer

The exponential reliability function is  $F^c(t) = e^{-t}$  for  $t \in [0, \infty)$ . After some algebra, the long term expected average cost per unit time is

$$C(s) = rac{a}{e^s - 1} + b, \quad s \in [0, \infty)$$
 (15.6.20)

But clearly C(s) is strictly decreasing in *s*, with limit *b*, so there is no minimum value.

The last result is hardly surprising. A device with an exponentially distributed lifetime does not age—if it has not failed, it's just as good as new. More generally, age replacement does not make sense for any device with decreasing failure rate. Such devices *improve* with age.

Suppose that the lifetime of the device (in appropriate units) has the gamma distribution with shape parameter 2 and scale parameter 1. Suppose that the costs (in appropriate units) are a = 1 and b = 5.

1. Find C(s).

# 2. Sketch the graph of C(s).

3. Solve numerically the optimal age replacement problem.

# Answer

The gamma reliability function is  $F^c(t) = e^{-t}(1+t)$  for  $t \in [0,\infty)$ 

1.

$$C(s)=rac{4+4s-5e^s}{2+s-2e^s}, \quad s\in(0,\infty)$$
 (15.6.21)

2.

The graph of 
$$C(s)$$
 on the interval  $(0,5]$ 

3. *C* is minimized for replacement time  $s \approx 1.3052$ . The optimal cost is about 2.26476.

Suppose again that the lifetime of the device (in appropriate units) has the gamma distribution with shape parameter 2 and scale parameter 1. But suppose now that the costs (in appropriate units) are a = 1 and b = 2.

1. Find C(s).

2. Sketch the graph of C(s).

3. Solve the optimal age replacement problem.

Answer

The gamma reliability function is  $F^c(t) = e^{-t}(1+t)$  for  $t \in [0,\infty)$ 

$$C(s) = rac{2e^s - (1+s)}{2e^s - (2+s)}, \quad s \in (0,\infty)$$
 (15.6.22)

2.

The graph of 
$$C(s)$$
 on the interval  $(0,4]$ 

3. *C* is strictly decreasing on 
$$[0, \infty)$$
 with limit 1, so there is no minimum value

In the last case, the difference between the cost of an emergency replacement and a planned replacement is not great enough for age replacement to make sense.

Suppose that the lifetime of the device (in appropriately scaled units) is uniformly distributed on the interval [0, 1]. Find C(s) and solve the optimal replacement problem. Give the results explicitly for the following costs:

1. a = 4, b = 62. a = 2, b = 53. a = 1, b = 10

# Proof

The reliability function is  $F^{c}(t) = 1 - t$  for  $t \in [0, 1]$ . After standard computations,

$$C(s) = 2 \frac{a(1-s)+bs}{s(2-s)}, \quad s \in (0,1]$$
 (15.6.23)

After more standard calculus, the optimal replacement time is

$$s = \frac{\sqrt{2ab - a^2} - a}{b - a} \tag{15.6.24}$$

1. 
$$s = 2 \left(\sqrt{2} - 1\right) \approx 0.828$$
 ,  $C \approx 11.657$   
2.  $s = \frac{2}{3}$  ,  $C = 9$   
3.  $s = \frac{\sqrt{19} - 1}{9} \approx 0.373$  ,  $C \approx 14.359$ 

# Thinning

We start with a standard renewal process with interarrival sequence  $\mathbf{X} = (X_1, X_2, ...)$ , arrival sequence  $\mathbf{T} = (T_0, T_1, ...)$  and counting process  $\mathbf{N} = \{N_t : t \in [0, \infty)\}$ . As usual, let  $\mu = \mathbb{E}(X)$  denote the mean of an interarrival time. For  $n \in \mathbb{N}_+$ , suppose

now that arrival n is either *accepted* or *rejected*, and define random variable  $Y_n$  to be 1 in the first case and 0 in the second. Let  $Z_n = (X_n, Y_n)$  denote the interarrival time and rejection variable pair for  $n \in \mathbb{N}_+$ , and assume that  $\mathbf{Z} = (Z_1, Z_2, ...)$  is an independent, identically distributed sequence.

Note that we have the structure of a renewal reward process, and so in particular,  $\mathbf{Y} = (Y_1, Y_2, ...)$  is a sequence of Bernoulli trials. Let p denote the parameter of this sequence, so that p is the probability of accepting an arrival. The procedure of accepting or rejecting points in a point process is known as *thinning* the point process. We studied thinning of the Poisson process. In the notation of this section, note that the reward process  $\mathbf{R} = \{R_t : t \in [0, \infty)\}$  is the thinned counting process. That is,

$$R_t = \sum_{i=1}^{N_t} Y_i \tag{15.6.25}$$

is the number of accepted points in [0, t] for  $t \in [0, \infty)$ . So then  $r(t) = \mathbb{E}(R_t)$  is the expected number of accepted points in [0, t]. The renewal reward theorem gives the asymptotic behavior.

Limits for the thinned process.

1.  $R_t/t o p/\mu$  as  $t o \infty$ 2.  $r(t)/t o p/\mu$  as  $t o \infty$ 

Proof

This follows immediately from the renewal reward theorem above, since  $\nu = p$ .

# **CHAPTER OVERVIEW**

# 16: Markov Processes

A Markov process is a random process in which the future is independent of the past, given the present. Thus, Markov processes are the natural stochastic analogs of the deterministic processes described by differential and difference equations. They form one of the most important classes of random processes.

# 16.1: Introduction to Markov Processes

A *Markov process* is a random process indexed by time, and with the property that the future is independent of the past, given the present. Markov processes, named for Andrei Markov, are among the most important of all random processes. In a sense, they are the stochastic analogs of differential equations and recurrence relations, which are of course, among the most important deterministic processes.

The complexity of the theory of Markov processes depends greatly on whether the time space T is  $\mathbb{N}$  (discrete time) or  $[0, \infty)$  (continuous time) and whether the state space is *discrete* (countable, with all subsets measurable) or a more general topological space. When  $T = [0, \infty)$  or when the state space is a general space, continuity assumptions usually need to be imposed in order to rule out various types of weird behavior that would otherwise complicate the theory.

When the state space is discrete, Markov processes are known as *Markov chains*. The general theory of Markov chains is mathematically rich and relatively simple.

- When  $T = \mathbb{N}$  and the state space is discrete, Markov processes are known as *discrete-time Markov chains*. The theory of such processes is mathematically elegant and complete, and is understandable with minimal reliance on measure theory. Indeed, the main tools are basic probability and linear algebra. Discrete-time Markov chains are studied in this chapter, along with a number of special models.
- When  $T = [0, \infty)$  and the state space is discrete, Markov processes are known as *continuous-time Markov chains*. If we avoid a few technical difficulties (created, as always, by the continuous time space), the theory of these processes is also reasonably simple and mathematically very nice. The Markov property implies that the process, sampled at the random times when the state changes, forms an embedded *discrete-time* Markov chain, so we can apply the theory that we will have already learned. The Markov property also implies that the holding time in a state has the memoryless property and thus must have an exponential distribution, a distribution that we know well. In terms of what you may have already studied, the Poisson process is a simple example of a continuous-time Markov chain.

For a general state space, the theory is more complicated and technical, as noted above. However, we can distinguish a couple of classes of Markov processes, depending again on whether the time space is discrete or continuous.

- When  $T = \mathbb{N}$  and  $S = \mathbb{R}$ , a simple example of a Markov process is the partial sum process associated with a sequence of independent, identically distributed real-valued random variables. Such sequences are studied in the chapter on random samples (but not as Markov processes), and revisited below.
- In the case that  $T = [0, \infty)$  and  $S = \mathbb{R}$  or more generally  $S = \mathbb{R}^k$ , the most important Markov processes are the *diffusion processes*. Generally, such processes can be constructed via stochastic differential equations from Brownian motion, which thus serves as the quintessential example of a Markov process in continuous time and space.

The goal of this section is to give a broad sketch of the general theory of Markov processes. Some of the statements are not completely rigorous and some of the proofs are omitted or are sketches, because we want to emphasize the main ideas without getting bogged down in technicalities. If you are a new student of probability you may want to just browse this section, to get the basic ideas and notation, but skipping over the proofs and technical details. Then jump ahead to the study of discrete-time Markov chains. On the other hand, to understand this section in more depth, you will need to review topcis in the chapter on foundations and in the chapter on stochastic processes.

# **Basic Theory**

# Preliminaries

As usual, our starting point is a probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ , so that  $\Omega$  is the set of outcomes,  $\mathscr{F}$  the  $\sigma$ -algebra of events, and  $\mathbb{P}$  the probability measure on  $(\Omega, \mathscr{F})$ . The time set T is either  $\mathbb{N}$  (discrete time) or  $[0, \infty)$  (continuous time). In the first case, T is given the discrete topology and in the second case T is given the usual Euclidean topology. In both cases, T is given the Borel  $\sigma$ -algebra  $\mathscr{T}$ , the  $\sigma$ -algebra generated by the open sets. In the discrete case when  $T = \mathbb{N}$ , this is simply the power set of T so that every subset of T is measurable; every function from T to another topological space is continuous. The time space  $(T, \mathscr{T})$  has a natural measure; counting measure # in the discrete case, and Lebesgue in the continuous case.

The set of states S also has a  $\sigma$ -algebra  $\mathscr{S}$  of admissible subsets, so that  $(S, \mathscr{S})$  is the *state space*. Usually S has a topology and  $\mathscr{S}$  is the Borel  $\sigma$ -algebra generated by the open sets. A typical set of assumptions is that the topology on S is *LCCB*: locally compact, Hausdorff, and with a countable base. These particular assumptions are general enough to capture all of the most important processes that occur in applications and yet are restrictive enough for a nice mathematical theory. Usually, there is a natural positive measure  $\lambda$  on the state space  $(S, \mathscr{S})$ . When S has an LCCB topology and  $\mathscr{S}$  is the Borel  $\sigma$ -algebra, the measure  $\lambda$  wil usually be a *Borel measure* satisfying  $\lambda(C) < \infty$  if  $C \subseteq S$  is compact. The term *discrete state space* means that S is countable with  $\mathscr{S} = \mathscr{P}(S)$ , the collection of all subsets of S. Thus every subset of S is measurable, as is every function from S to another measurable space. This is the Borel  $\sigma$ -algebra for the discrete topology on S, so that every function from S to another topological space is continuous. The compact sets are simply the finite sets, and the reference measure is #, counting measure. If  $S = \mathbb{R}^k$  for some  $k \in S$  (another common case), then we usually give S the Euclidean topology (which is LCCB) so that  $\mathscr{S}$  is the usual Borel  $\sigma$ -algebra. The compact sets are the closed, bounded sets, and the reference measure.

Clearly, the topological and measure structures on T are not really necessary when  $T = \mathbb{N}$ , and similarly these structures on S are not necessary when S is countable. But the main point is that the assumptions unify the discrete and the common continuous cases. Also, it should be noted that much more general state spaces (and more general time spaces) are possible, but most of the important Markov processes that occur in applications fit the setting we have described here.

Various spaces of real-valued functions on S play an important role. Let  $\mathscr{B}$  denote the collection of bounded, measurable functions  $f: S \to \mathbb{R}$ . With the usual (pointwise) addition and scalar multiplication,  $\mathscr{B}$  is a vector space. We give  $\mathscr{B}$  the supremum norm, defined by  $||f|| = \sup\{|f(x)| : x \in S\}$ .

Suppose now that  $\mathbf{X} = \{X_t : t \in T\}$  is a stochastic process on  $(\Omega, \mathscr{F}, \mathbb{P})$  with state space S and time space T. Thus,  $X_t$  is a random variable taking values in S for each  $t \in T$ , and we think of  $X_t \in S$  as the *state* of a system at *time*  $t \in T$ . We also assume that we have a collection  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$  of  $\sigma$ -algebras with the properties that  $X_t$  is measurable with respect to  $\mathscr{F}_t$  for  $t \in T$ , and the  $\mathscr{F}_s \subseteq \mathscr{F}_t \subseteq \mathscr{F}$  for  $s, t \in T$  with  $s \leq t$ . Intuitively,  $\mathscr{F}_t$  is the collection of event up to time  $t \in T$ . Technically, the assumptions mean that  $\mathfrak{F}$  is a filtration and that the process  $\mathbf{X}$  is *adapted* to  $\mathfrak{F}$ . The most basic (and coarsest) filtration is the *natural filtration*  $\mathfrak{F}^0 = \{\mathscr{F}_t^0 : t \in T\}$  where  $\mathscr{F}_t^0 = \sigma\{X_s : s \in T, s \leq t\}$ , the  $\sigma$ -algebra generated by the process up to time  $t \in T$ . In continuous time, however, it is often necessary to use slightly finer  $\sigma$ -algebras in order to have a nice mathematical theory. In particular, we often need to assume that the filtration  $\mathfrak{F}$  is *right continuous* in the sense that  $\mathscr{F}_{t+} = \mathscr{F}_t$  for  $t \in T$  where  $\mathscr{F}_{t+} = \bigcap\{\mathscr{F}_s : s \in T, s > t\}$ . We can accomplish this by taking  $\mathfrak{F} = \mathfrak{F}_+^0$  so that  $\mathscr{F}_t = \mathscr{F}_t^0$  for  $t \in T$ , and in this case,  $\mathfrak{F}$  is referred to as the *right continuous refinement* of the natural filtration. We also sometimes need to assume that  $\mathfrak{F}$  is complete with respect to  $\mathbb{P}$  in the sense that if  $A \in \mathscr{F}$  with  $\mathbb{P}(A) = 0$  and  $B \subseteq A$  then  $B \in \mathscr{F}_0$ . That is,  $\mathscr{F}_0$  contains all of the *null events* (and hence also all of the *almost certain* events), and therefore so does  $\mathscr{F}_t$  for all  $t \in T$ .

# Definitions

The random process X is a *Markov process* if

$$\mathbb{P}(X_{s+t} \in A \mid \mathscr{F}_s) = \mathbb{P}(X_{s+t} \in A \mid X_s)$$
(16.1.1)

for all  $s, t \in T$  and  $A \in \mathscr{S}$ .

The defining condition, known appropriately enough as the the *Markov property*, states that the conditional distribution of  $X_{s+t}$  given  $\mathscr{F}_s$  is the same as the conditional distribution of  $X_{s+t}$  just given  $X_s$ . Think of s as the present time, so that s+t is a time in the future. If we know the present state  $X_s$ , then any additional knowledge of events in the past is irrelevant in terms of predicting the future state  $X_{s+t}$ . Technically, the conditional probabilities in the definition are random variables, and the equality must be interpreted as holding with probability 1. As you may recall, conditional expected value is a more general and useful concept than conditional probability, so the following theorem may come as no surprise.

The random process  $\boldsymbol{X}$  is a Markov process if and only if

$$\mathbb{E}[f(X_{s+t}) \mid \mathscr{F}_s] = \mathbb{E}[f(X_{s+t}) \mid X_s]$$
(16.1.2)

for every  $s, t \in T$  and every  $f \in \mathscr{B}$ .

Proof sketch

The condition in this theorem clearly implies the Markov property, by letting  $f = \mathbf{1}_A$ , the indicator function of  $A \in \mathscr{S}$ . The converse is a classical bootstrapping argument: the Markov property implies the expected value condition

1. First when  $f = \mathbf{1}_A$  for  $A \in \mathscr{S}$  (by definition).

2. Next when  $f \in \mathscr{B}$  is a simple function, by linearity.

3. Next when  $f \in \mathscr{B}$  is nonnegative, by the monotone convergence theorem.

4. Finally for general  $f \in \mathscr{B}$  by considering positive and negative parts.

Technically, we should say that X is a Markov process *relative to* the filtration  $\mathfrak{F}$ . If X satisfies the Markov property relative to a filtration, then it satisfies the Markov property relative to any coarser filtration.

Suppose that the stochastic process  $X = \{X_t : t \in T\}$  is adapted to the filtration  $\mathfrak{F} = \{\mathscr{P}_t : t \in T\}$  and that  $\mathfrak{G} = \{\mathscr{G}_t : t \in T\}$  is a filtration that is finer than  $\mathfrak{F}$ . If X is a Markov process relative to  $\mathfrak{G}$  then X is a Markov process relative to  $\mathfrak{F}$ .

Proof

First recall that  $m{X}$  is adapted to  $\mathfrak{G}$  since  $m{X}$  is adapted to  $\mathfrak{F}.$  If  $s,\,t\in T$  and  $f\in\mathscr{B}$  then

$$\mathbb{E}[f(X_{s+t}) \mid \mathscr{F}_s] = \mathbb{E}\left(\mathbb{E}[f(X_{s+t}) \mid \mathscr{G}_s] \mid \mathscr{F}_s\right) = \mathbb{E}\left(\mathbb{E}[f(X_{s+t}) \mid X_s] \mid \mathscr{F}_s\right) = \mathbb{E}[f(X_{s+t}) \mid X_s]$$
(16.1.3)

The first equality is a basic property of conditional expected value. The second uses the fact that X is Markov relative to  $\mathfrak{G}$ , and the third follows since  $X_s$  is measurable with respect to  $\mathscr{F}_s$ .

In particular, if X is a Markov process, then X satisfies the Markov property relative to the natural filtration  $\mathfrak{F}^0$ . The theory of Markov processes is simplified considerably if we add an additional assumption.

A Markov process  $\boldsymbol{X}$  is time homogeneous if

$$\mathbb{P}(X_{s+t} \in A \mid X_s = x) = \mathbb{P}(X_t \in A \mid X_0 = x)$$
(16.1.4)

for every  $s,\,t\in T$  ,  $x\in S$  and  $A\in\mathscr{S}.$ 

So if X is homogeneous (we usually don't bother with the *time* adjective), then the process  $\{X_{s+t} : t \in T\}$  given  $X_s = x$  is equivalent (in distribution) to the process  $\{X_t : t \in T\}$  given  $X_0 = x$ . For this reason, the initial distribution is often unspecified in the study of Markov processes—if the process

is in state  $x \in S$  at a particular time  $s \in T$ , then it doesn't really matter how the process got to state x; the process essentially "starts over", independently of the past. The term *stationary* is sometimes used instead of homogeneous.

From now on, we will usually assume that our Markov processes are homogeneous. This is not as big of a loss of generality as you might think. A non-homogeneous process can be turned into a homogeneous process by enlarging the state space, as shown below. For a homogeneous Markov process, if  $s, t \in T, x \in S$ , and  $f \in \mathcal{B}$ , then

$$\mathbb{E}[f(X_{s+t}) \mid X_s = x] = \mathbb{E}[f(X_t) \mid X_0 = x]$$
(16.1.5)

# Feller Processes

In continuous time, or with general state spaces, Markov processes can be very strange without additional continuity assumptions. Suppose (as is usually the case) that S has an LCCB topology and that  $\mathscr{S}$  is the Borel  $\sigma$ -algebra. Let  $\mathscr{C}$  denote the collection of bounded, continuous functions  $f: S \to \mathbb{R}$ . Let  $\mathscr{C}_0$  denote the collection of continuous functions  $f: S \to \mathbb{R}$  that *vanish at*  $\infty$ . The last phrase means that for every  $\epsilon > 0$ , there exists a compact set  $C \subseteq S$  such that  $|f(x)| < \epsilon$  if  $x \notin C$ . With the usual (pointwise) operations of addition and scalar multiplication,  $\mathscr{C}_0$  is a vector subspace of  $\mathscr{C}$ , which in turn is a vector subspace of  $\mathscr{B}$ . Just as with  $\mathscr{B}$ , the supremum norm is used for  $\mathscr{C}$  and  $\mathscr{C}_0$ .

A Markov process  $X = \{X_t : t \in T\}$  is a *Feller process* if the following conditions are satisfied.

- 1. *Continuity in space*: For  $t \in T$  and  $y \in S$ , the distribution of  $X_t$  given  $X_0 = x$  converges to the distribution of  $X_t$  given  $X_0 = y$  as  $x \to y$ .
- 2. *Continuity in time*: Given  $X_0 = x$  for  $x \in S$ ,  $X_t$  converges in probability to x as  $t \downarrow 0$ .

Additional details

- 1. This means that  $\mathbb{E}[f(X_t) \mid X_0 = x] \to \mathbb{E}[f(X_t) \mid X_0 = y]$  as  $x \to y$  for every  $f \in \mathscr{C}$ .
- 2. This means that  $\mathbb{P}[X_t \in U \mid X_0 = x] \to 1$  as  $t \downarrow 0$  for every neighborhood U of x.

Feller processes are named for William Feller. Note that if S is discrete, (a) is automatically satisfied and if T is discrete, (b) is automatically satisfied. In particular, every discrete-time Markov chain is a Feller Markov process. There are certainly more general Markov processes, but most of the important processes that occur in applications are Feller processes, and a number of nice properties flow from the assumptions. Here is the first:

If  $X = \{X_t : t \in T\}$  is a Feller process, then there is a version of X such that  $t \mapsto X_t(\omega)$  is continuous from the right and has left limits for every  $\omega \in \Omega$ .

Again, this result is only interesting in continuous time  $T = [0, \infty)$ . Recall that for  $\omega \in \Omega$ , the function  $t \mapsto X_t(\omega)$  is a *sample path* of the process. So we will often assume that a Feller Markov process has sample paths that are right continuous have left limits, since we know there is a version with these properties.

# Stopping Times and the Strong Markov Property

For our next discussion, you may need to review again the section on filtrations and stopping times. To give a quick review, suppose again that we start with our probability space  $(\Omega, \mathscr{F}, \mathbb{P})$  and the filtration  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$  (so that we have a *filtered probability space*).

Since time (past, present, future) plays such a fundamental role in Markov processes, it should come as no surprise that random times are important. We often need to allow random times to take the value  $\infty$ , so we need to enlarge the set of times to  $T_{\infty} = T \cup \{\infty\}$ . The topology on T is extended to  $T_{\infty}$  by the rule that for  $s \in T$ , the set  $\{t \in T_{\infty} : t > s\}$  is an open neighborhood of  $\infty$ . This is the one-point compactification of T and is used so that the notion of *time converging to infinity* is preserved. The Borel  $\sigma$ -algebra  $\mathscr{T}_{\infty}$  is used on  $T_{\infty}$ , which again is just the power set in the discrete case.

If  $\mathbf{X} = \{X_t : t \in T\}$  is a stochastic process on the sample space  $(\Omega, \mathscr{F})$ , and if  $\tau$  is a random time, then naturally we want to consider the state  $X_{\tau}$  at the random time. There are two problems. First if  $\tau$  takes the value  $\infty, X_{\tau}$  is not defined. The usual solution is to add a new "death state"  $\delta$  to the set of states S, and then to give  $S_{\delta} = S \cup \{\delta\}$  the  $\sigma$  algebra  $\mathscr{S}_{\delta} = \mathscr{S} \cup \{A \cup \{\delta\} : A \in \mathscr{S}\}$ . A function  $f \in \mathscr{B}$  is extended to  $S_{\delta}$  by the rule  $f(\delta) = 0$ . The second problem is that  $X_{\tau}$  may not be a valid random variable (that is, measurable) unless we assume that the stochastic process  $\mathbf{X}$  is measurable. Recall that this means that  $\mathbf{X} : \Omega \times T \to S$  is measurable relative to  $\mathscr{F} \otimes \mathscr{T}$  and  $\mathscr{S}$ . (This is always true in discrete time.)

Recall next that a random time  $\tau$  is a stopping time (also called a *Markov time* or an *optional time*) relative to  $\mathfrak{F}$  if  $\{\tau \leq t\} \in \mathscr{F}_t$  for each  $t \in T$ . Intuitively, we can tell whether or not  $\tau \leq t$  from the information available to us at time t. In a sense, a stopping time is a random time that does not require that we see into the future. Of course, the concept depends critically on the filtration. Recall that if a random time  $\tau$  is a stopping time for a filtration  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$  then it is also a stopping time for a finer filtration  $\mathfrak{G} = \{\mathscr{G}_t : t \in T\}$ , so that  $\mathscr{F}_t \subseteq \mathscr{G}_t$  for  $t \in T$ . Thus, the finer the filtration, the larger the collection of stopping times. In fact if the filtration is the trivial one where  $\mathscr{F}_t = \mathscr{F}$  for all  $t \in T$  (so that all information is available to us from the beginning of time), then *any* random time is a stopping time. But of course, this trivial filtration is usually not sensible.

Next, recall that if  $\tau$  is a stopping time for the filtration  $\mathfrak{F}$ , then the  $\sigma$ -algebra  $\mathscr{F}_{\tau}$  associated with  $\tau$  is given by

$$\mathscr{F}_{\tau} = \{A \in \mathscr{F} : A \cap \{\tau \leq t\} \in \mathscr{F}_t \text{ for all } t \in T\}$$

$$(16.1.6)$$

Intuitively,  $\mathscr{F}_{\tau}$  is the collection of events up to the random time  $\tau$ , analogous to the  $\mathscr{F}_t$  which is the collection of events up to the deterministic time  $t \in T$ . If  $\mathbf{X} = \{X_t : t \in T\}$  is a stochastic process adapted to  $\mathfrak{F}$  and if  $\tau$  is a stopping time relative to  $\mathfrak{F}$ , then we would hope that  $X_{\tau}$  is measurable with respect to  $\mathscr{F}_{\tau}$  just as  $X_t$  is measurable with respect to  $\mathscr{F}_t$  for deterministic  $t \in T$ . However, this will generally not be the case unless  $\mathbf{X}$  is progressively measurable relative to  $\mathfrak{F}$ , which means that  $\mathbf{X} : \Omega \times T_t \to S$  is measurable with respect to  $\mathscr{F}_t \otimes \mathscr{T}_t$  and  $\mathscr{S}$  where  $T_t = \{s \in T : s \leq t\}$ 

and  $\mathscr{T}_t$  the corresponding Borel  $\sigma$ -algebra. This is always true in discrete time, of course, and more generally if *S* has an LCCB topology with  $\mathscr{S}$  the Borel  $\sigma$ -algebra, and *X* is right continuous. If *X* is progressively measurable with respect to  $\mathfrak{F}$  then *X* is measurable and *X* is adapted to  $\mathfrak{F}$ .

The *strong Markov property* for our stochastic process  $X = \{X_t : t \in T\}$  states that the future is independent of the past, given the present, when the present time is a stopping time.

The random process  $\boldsymbol{X}$  is a strong Markov process if

$$\mathbb{E}[f(X_{\tau+t}) \mid \mathscr{F}_{\tau}] = \mathbb{E}[f(X_{\tau+t}) \mid X_{\tau}]$$
(16.1.7)

for every  $t\in T$  , stopping time au , and  $f\in \mathscr{B}.$ 

As with the regular Markov property, the strong Markov property depends on the underlying filtration  $\mathfrak{F}$ . If the property holds with respect to a given filtration, then it holds with respect to a coarser filtration.

Suppose that the stochastic process  $X = \{X_t : t \in T\}$  is progressively measurable relative to the filtration  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$  and that the filtration  $\mathfrak{G} = \{\mathscr{G}_t : t \in T\}$  is finer than  $\mathfrak{F}$ . If X is a strong Markov process relative to  $\mathfrak{G}$  then X is a strong Markov process relative to  $\mathfrak{F}$ .

Proof

Recall again that since X is adapted to  $\mathfrak{F}$ , it is also adapted to  $\mathfrak{G}$ . Suppose that  $\tau$  is a finite stopping time for  $\mathfrak{F}$  and that  $t \in T$  and  $f \in \mathscr{B}$ . Then  $\tau$  is also a stopping time for  $\mathfrak{G}$ , and  $\mathscr{F}_{\tau} \subseteq \mathscr{G}_{\tau}$ . Hence

 $\mathbb{E}[f(X_{\tau+t}) \mid \mathscr{F}_{\tau}] = \mathbb{E}\left(\mathbb{E}[f(X_{\tau+t}) \mid \mathscr{G}_{\tau}] \mid \mathscr{F}_{\tau}\right) = \mathbb{E}\left(\mathbb{E}[f(X_{\tau+t}) \mid X_{\tau}] \mid \mathscr{F}_{\tau}\right) = \mathbb{E}[f(X_{\tau+t}) \mid X_{\tau}]$ (16.1.8)

The first equality is a basic property of conditional expected value. The second uses the fact that X has the strong Markov property relative to  $\mathfrak{G}$ , and the third follows since  $X_{\tau}$  measurable with respect to  $\mathscr{F}_{\tau}$ . In continuous time, it's last step that requires progressive measurability.

So if *X* is a strong Markov process, then *X* satisfies the strong Markov property relative to its natural filtration. Again there is a tradeoff: finer filtrations allow more stopping times (generally a good thing), but make the strong Markov property harder to satisfy and may not be reasonable (not so good). So we usually don't want filtrations that are too much finer than the natural one.

With the strong Markov and homogeneous properties, the process  $\{X_{\tau+t} : t \in T\}$  given  $X_{\tau} = x$  is equivalent in distribution to the process  $\{X_t : t \in T\}$  given  $X_0 = x$ . Clearly, the strong Markov property implies the ordinary Markov property, since a fixed time  $t \in T$  is trivially also a stopping time. The converse is true in discrete time.

Suppose that  $X = \{X_n : n \in \mathbb{N}\}$  is a (homogeneous) Markov process in discrete time. Then X is a strong Markov process.

As always in continuous time, the situation is more complicated and depends on the continuity of the process X and the filtration  $\mathfrak{F}$ . Here is the standard result for Feller processes.

If  $\mathbf{X} = \{X_t : t \in [0, \infty) \text{ is a Feller Markov process, then } \mathbf{X} \text{ is a strong Markov process relative to filtration } \mathfrak{F}^0_+$ , the right-continuous refinement of the natural filtration.

# **Transition Kernels of Markov Processes**

For our next discussion, you may need to review the section on kernels and operators in the chapter on expected value. Suppose again that  $X = \{X_t : t \in T\}$  is a (homogeneous) Markov process with state space *S* and time space *T*, as described above. The kernels in the following definition are of fundamental importance in the study of *X* 

For  $t \in T$  , let

$$P_t(x,A) = \mathbb{P}(X_t \in A \mid X_0 = x), \quad x \in S, A \in \mathscr{S}$$

$$(16.1.9)$$

Then  $P_t$  is a probability kernel on  $(S, \mathscr{S})$ , known as the *transition kernel* of X for time t.

Proof

Fix  $t \in T$ . The measurability of  $x \mapsto \mathbb{P}(X_t \in A \mid X_0 = x)$  for  $A \in \mathscr{S}$  is built into the definition of conditional probability. Also, of course,  $A \mapsto \mathbb{P}(X_t \in A \mid X_0 = x)$  is a probability measure on  $\mathscr{S}$  for  $x \in S$ . In general, the conditional distribution of one random variable, conditioned on a value of another random variable defines a probability kernel.

That is,  $P_t(x, \cdot)$  is the conditional distribution of  $X_t$  given  $X_0 = x$  for  $t \in T$  and  $x \in S$ . By the time homogenous property,  $P_t(x, \cdot)$  is also the conditional distribution of  $X_{s+t}$  given  $X_s = x$  for  $s \in T$ :

$$P_t(x,A) = \mathbb{P}(X_{s+t} \in A \mid X_s = x), \quad s, t \in T, x \in S, A \in \mathscr{S}$$

$$(16.1.10)$$

Note that  $P_0 = I$ , the *identity kernel* on  $(S, \mathscr{S})$  defined by  $I(x, A) = \mathbf{1}(x \in A)$  for  $x \in S$  and  $A \in \mathscr{S}$ , so that I(x, A) = 1 if  $x \in A$  and I(x, A) = 0 if  $x \notin A$ . Recall also that usually there is a natural reference measure  $\lambda$  on  $(S, \mathscr{S})$ . In this case, the transition kernel  $P_t$  will often have a *transition density*  $p_t$  with respect to  $\lambda$  for  $t \in T$ . That is,

$$P_t(x,A)=\mathbb{P}(X_t\in A\mid X_0=x)=\int_A p_t(x,y)\lambda(dy), \hspace{1em} x\in S, \hspace{1em} A\in\mathscr{S} \hspace{1em} (16.1.11)$$

The next theorem gives the *Chapman-Kolmogorov* equation, named for Sydney Chapman and Andrei Kolmogorov, the fundamental relationship between the probability kernels, and the reason for the name *transition kernel*.

Suppose again that  $\mathbf{X} = \{X_t : t \in T\}$  is a Markov process on S with transition kernels  $\mathbf{P} = \{P_t : t \in T\}$ . If  $s, s \in T$ , then  $P_sP_t = P_{s+t}$ . That is,

$$P_{s+t}(x,A) = \int_{S} P_s(x,dy) P_t(y,A), \quad x \in S, A \in \mathscr{S}$$
(16.1.12)

Proof

The Markov property and a conditioning argument are the fundamental tools. Recall again that  $P_s(x, \cdot)$  is the conditional distribution of  $X_s$  given  $X_0 = x$  for  $x \in S$ . Let  $A \in \mathscr{S}$ . Conditioning on  $X_s$  gives

$$P_{s+t}(x,A) = \mathbb{P}(X_{s+t} \in A \mid X_0 = x) = \int_S P_s(x,dy) \mathbb{P}(X_{s+t} \in A \mid X_s = y, X_0 = x)$$
(16.1.13)

But by the Markov and time-homogeneous properties,

$$\mathbb{P}(X_{s+t} \in A \mid X_s = y, X_0 = x) = \mathbb{P}(X_t \in A \mid X_0 = y) = P_t(y, A)$$
(16.1.14)

Substituting we have

$$P_{s+t}(x,A) = \int_{S} P_s(x,dy) P_t(y,A) = (P_s P_t)(x,A)$$
(16.1.15)

In the language of functional analysis, P is a *semigroup*. Recall that the commutative property generally does not hold for the product operation on kernels. However the property does hold for the transition kernels of a homogeneous Markov process. That is,  $P_sP_t = P_tP_s = P_{s+t}$  for  $s, t \in T$ . As a simple corollary, if S has a reference measure, the same basic relationship holds for the transition densities.

Suppose that  $\lambda$  is the reference measure on  $(S, \mathscr{S})$  and that  $\mathbf{X} = \{X_t : t \in T\}$  is a Markov process on S and with transition densities  $\{p_t : t \in T\}$ . If  $s, t \in T$  then  $p_s p_t = p_{s+t}$ . That is,

$$p_t(x,z) = \int_S p_s(x,y) p_t(y,z) \lambda(dy), \quad x, z \in S$$

$$(16.1.16)$$

Proof

The transition kernels satisfy  $P_s P_t = P_{s+t}$ . But  $P_s$  has density  $p_s$ ,  $P_t$  has density  $p_t$ , and  $P_{s+t}$  has density  $p_{s+t}$ . From a basic result on kernel functions,  $P_s P_t$  has density  $p_s p_t$  as defined in the theorem.

If  $T = \mathbb{N}$  (discrete time), then the transition kernels of X are just the powers of the *one-step* transition kernel. That is, if we let  $P = P_1$  then  $P_n = P^n$  for  $n \in \mathbb{N}$ .

Recall that a kernel defines two operations: operating on the left with positive measures on  $(S, \mathscr{S})$  and operating on the right with measurable, real-valued functions. For the transition kernels of a Markov process, both of the these operators have natural interpretations.

Suppose that  $s, t \in T$ . If  $\mu_s$  is the distribution of  $X_s$  then  $X_{s+t}$  has distribution  $\mu_{s+t} = \mu_s P_t$ . That is,

$$\mu_{s+t}(A) = \int_{S} \mu_s(dx) P_t(x, A), \quad A \in \mathscr{S}$$
(16.1.17)

Proof

Let  $A \in \mathscr{S}$ . Conditioning on  $X_s$  gives

$$\mathbb{P}(X_{s+t} \in A) = \mathbb{E}[\mathbb{P}(X_{s+t} \in A \mid X_s)] = \int_S \mu_s(dx) \mathbb{P}(X_{s+t} \in A \mid X_s = x) = \int_S \mu_s(dx) P_t(x, A) = \mu_s P_t(A)$$
(16.1.18)

So if  $\mathscr{P}$  denotes the collection of probability measures on  $(S, \mathscr{S})$ , then the left operator  $P_t$  maps  $\mathscr{P}$  back into  $\mathscr{P}$ . In particular, if  $X_0$  has distribution  $\mu_0$  (the *initial distribution*) then  $X_t$  has distribution  $\mu_t = \mu_0 P_t$  for every  $t \in T$ .

A positive measure  $\mu$  on  $(S, \mathscr{S})$  is *invariant* for  $\boldsymbol{X}$  if  $\mu P_t = \mu$  for every  $t \in T$ .

Hence if  $\mu$  is a probability measure that is invariant for X, and  $X_0$  has distribution  $\mu$ , then  $X_t$  has distribution  $\mu$  for every  $t \in T$  so that the process X is identically distributed. In discrete time, note that if  $\mu$  is a positive measure and  $\mu P = \mu$  then  $\mu P^n = \mu$  for every  $n \in \mathbb{N}$ , so  $\mu$  is invariant for X. The operator on the right is given next.

Suppose that  $f: S \to \mathbb{R}$  . If  $t \in T$  then (assuming that the expected value exists),

$$P_t f(x) = \int_S P_t(x, dy) f(y) = \mathbb{E} \left[ f(X_t) \mid X_0 = x 
ight], \quad x \in S$$
 (16.1.19)

Proof

This follows directly from the definitions:

$$P_t f(x) = \int_S P_t(x, dy) f(y), \quad x \in S$$
 (16.1.20)

and  $P_t(x, \cdot)$  is the conditional distribution of  $X_t$  given  $X_0 = x$ .

In particular, the right operator  $P_t$  is defined on  $\mathscr{B}$ , the vector space of bounded, linear functions  $f : S \to \mathbb{R}$ , and in fact is a linear operator on  $\mathscr{B}$ . That is, if  $f, g \in \mathscr{B}$  and  $c \in \mathbb{R}$ , then  $P_t(f+g) = P_t f + P_t g$  and  $P_t(cf) = cP_t f$ . Moreover,  $P_t$  is a *contraction operator* on  $\mathscr{B}$ , since  $||P_t f|| \le ||f||$  for  $f \in \mathscr{B}$ . It then follows that  $P_t$  is a continuous operator on  $\mathscr{B}$  for  $t \in T$ .

For the right operator, there is a concept that is complementary to the invariance of of a positive measure for the left operator.

A measurable function  $f : S \to \mathbb{R}$  is *harmonic* for **X** if  $P_t f = f$  for all  $t \in T$ .

Again, in discrete time, if Pf = f then  $P^n f = f$  for all  $n \in \mathbb{N}$ , so f is harmonic for X.

Combining two results above, if  $X_0$  has distribution  $\mu_0$  and  $f: S \to \mathbb{R}$  is measurable, then (again assuming that the expected value exists),  $\mu_0 P_t f = \mathbb{E}[f(X_t)]$  for  $t \in T$ . That is,

$$\mathbb{E}[f(X_t)] = \int_S \mu_0(dx) \int_S P_t(x, dy) f(y)$$
(16.1.21)

The result above shows how to obtain the distribution of  $X_t$  from the distribution of  $X_0$  and the transition kernel  $P_t$  for  $t \in T$ . But we can do more. Recall that one basic way to describe a stochastic process is to give its *finite dimensional distributions*, that is, the distribution of  $(X_{t_1}, X_{t_2}, \ldots, X_{t_n})$  for every  $n \in \mathbb{N}_+$  and every  $(t_1, t_2, \ldots, t_n) \in T^n$ . For a Markov process, the initial distribution and the transition kernels determine the finite dimensional distributions. It's easiest to state the distributions in differential form.

Suppose  $X = \{X_t : t \in T\}$  is a Markov process with transition operators  $P = \{P_t : t \in T\}$ , and that  $(t_1, \ldots, t_n) \in T^n$  with  $0 < t_1 < \cdots < t_n$ . If  $X_0$  has distribution  $\mu_0$ , then in differential form, the distribution of  $(X_0, X_{t_1}, \ldots, X_{t_n})$  is

$$\mu_0(dx_0)P_{t_1}(x_0, dx_1)P_{t_2-t_1}(x_1, dx_2)\cdots P_{t_n-t_{n-1}}(x_{n-1}, dx_n)$$
(16.1.22)

Proof

This follows from induction and repeated use of the Markov property. For example, if  $t \in T$  with t > 0, then conditioning on  $X_0$  gives

$$\mathbb{P}(X_0 \in A, X_t \in B) = \int_A \mathbb{P}(X_t \in B \mid X_0 = x)\mu_0(dx) = \int_A P_t(x, B)\mu(dx) = \int_A \int_B P_t(x, dy)\mu_0(dx)$$
(16.1.23)

for  $A, B \in \mathscr{S}$ . So in differential form, the distribution of  $(X_0, X_t)$  is  $\mu(dx)P_t(x, dy)$ . If  $s, t \in T$  with 0 < s < t, then conditioning on  $(X_0, X_s)$  and using our previous result gives

$$\mathbb{P}(X_0 \in A, X_s \in B, X_t \in C) = \int_{A \times B} \mathbb{P}(X_t \in C \mid X_0 = x, X_s = y) \mu_0(dx) P_s(x, dy)$$
(16.1.24)

for  $A, B, C \in \mathscr{S}$ . But by the Markov property,

$$\mathbb{P}(X_t \in C \mid X_0 = x, X_s = y) = \mathbb{P}(X_t \in C \mid X_s = y) = P_{t-s}(y, C) = \int_C P_{t-s}(y, dz)$$
(16.1.25)

Hence in differential form, the distribution of  $(X_0, X_s, X_t)$  is  $\mu_0(dx)P_s(x, dy)P_{t-s}(y, dz)$ . Continuing in this manner gives the general result.

This result is very important for constructing Markov processes. If we know how to define the transition kernels  $P_t$  for  $t \in T$  (based on modeling considerations, for example), and if we know the initial distribution  $\mu_0$ , then the last result gives a consistent set of finite dimensional distributions. From the Kolmogorov construction theorem, we know that there *exists* a stochastic process that has these finite dimensional distributions. In continuous time, however, two serious problems remain. First, it's not clear how we would construct the transition kernels so that the crucial Chapman-Kolmogorov equations above are satisfied. Second, we usually want our Markov process to have certain properties (such as continuity properties of the sample paths) that go beyond the finite dimensional distributions. The first problem will be addressed in the next section, and fortunately, the second problem can be resolved for a Feller process.

Suppose that  $X = \{X_t : t \in T\}$  is a Markov process on an LCCB state space  $(S, \mathscr{S})$  with transition operators  $P = \{P_t : t \in [0, \infty)\}$ . Then X is a Feller process if and only if the following conditions hold:

- 1. Continuity in space: If  $f \in \mathscr{C}_0$  and  $t \in [0, \infty)$  then  $P_t f \in \mathscr{C}_0$
- 2. *Continuity in time*: If  $f \in \mathscr{C}_0$  and  $x \in S$  then  $P_t f(x) \to f(x)$  as  $t \downarrow 0$ .

A semigroup of probability kernels  $P = \{P_t : t \in T\}$  that satisfies the properties in this theorem is called a *Feller* semigroup. So the theorem states that the *Markov process* X is Feller if and only if the *transition semigroup of transition* P is Feller. As before, (a) is automatically satisfied if S is discrete, and (b) is automatically satisfied if T is discrete. Condition (a) means that  $P_t$  is an operator on the vector space  $C_0$ , in addition to being an operator on the larger space  $\mathcal{B}$ . Condition (b) actually implies a stronger form of continuity in time.

Suppose that  $P = \{P_t : t \in T\}$  is a Feller semigroup of transition operators. Then  $t \mapsto P_t f$  is continuous (with respect to the supremum norm) for  $f \in \mathscr{C}_0$ .

Additional details

This means that for  $f \in \mathscr{C}_0$  and  $t \in [0, \infty)$ ,

$$||P_{t+s}f - P_tf|| = \sup\{|P_{t+s}f(x) - P_tf(x)| : x \in S\} \to 0 \text{ as } s \to 0$$
(16.1.26)

So combining this with the remark above, note that if P is a Feller semigroup of transition operators, then  $f \mapsto P_t f$  is continuous on  $\mathcal{C}_0$  for fixed  $t \in T$ , and  $t \mapsto P_t f$  is continuous on T for fixed  $f \in \mathcal{C}_0$ . Again, the importance of this is that we often start with the collection of probability kernels P and want to know that there exists a nice Markov process X that has these transition operators.

# Sampling in Time

If we *sample* a Markov process at an increasing sequence of points in time, we get another Markov process in discrete time. But the discrete time process may not be homogeneous even if the original process is homogeneous.

Suppose that  $X = \{X_t : t \in T\}$  is a Markov process with state space  $(S, \mathscr{S})$  and that  $(t_0, t_1, t_2, ...)$  is a sequence in T with  $0 = t_0 < t_1 < t_2 < \cdots$ . Let  $Y_n = X_{t_n}$  for  $n \in \mathbb{N}$ . Then  $Y = \{Y_n : n \in \mathbb{N}\}$  is a Markov process in discrete time. Proof

For  $n \in \mathbb{N}$ , let  $\mathscr{G}_n = \sigma\{Y_k : k \in \mathbb{N}, k \leq n\}$ , so that  $\{\mathscr{G}_n : n \in \mathbb{N}\}$  is the natural filtration associated with Y. Note that  $\mathscr{G}_n \subseteq \mathscr{F}_{t_n}$  and  $Y_n = X_{t_n}$  is measurable with respect to  $\mathscr{G}_n$  for  $n \in \mathbb{N}$ . Let  $k, n \in \mathbb{N}$  and let  $A \in \mathscr{S}$ . Then

$$\mathbb{P}\left(Y_{k+n} \in A \mid \mathscr{G}_{k}\right) = \mathbb{P}\left(X_{t_{n+k}} \in A \mid \mathscr{G}_{k}\right) = \mathbb{P}\left(X_{t_{n+k}} \in A \mid X_{t_{k}}\right) = \mathbb{P}\left(Y_{n+k} \in A \mid Y_{k}\right)$$
(16.1.27)

If we sample a homogeneous Markov process at multiples of a fixed, positive time, we get a homogenous Markov process in discrete time.

Suppose that  $X = \{X_t : t \in T\}$  is a homogeneous Markov process with state space  $(S, \mathscr{S})$  and transition kernels  $P = \{P_t : t \in T\}$ . Fix  $r \in T$  with r > 0 and define  $Y_n = X_{nr}$  for  $n \in \mathbb{N}$ . Then  $Y = \{Y_n : n \in \mathbb{N}\}$  is a homogeneous Markov process in discrete time, with one-step transition kernel Q given by

$$Q(x,A) = P_r(x,A); \quad x \in S, \ A \in \mathscr{S}$$
 (16.1.28)

In some cases, sampling a strong Markov process at an increasing sequence of stopping times yields another Markov process in discrete time. The point of this is that discrete-time Markov processes are often found naturally embedded in continuous-time Markov processes.

# Enlarging the State Space

Our first result in this discussion is that a non-homogeneous Markov process can be turned into a homogenous Markov process, but only at the expense of enlarging the state space.

Suppose that  $X = \{X_t : t \in T\}$  is a non-homogeneous Markov process with state space  $(S, \mathscr{S})$ . Suppose also that  $\tau$  is a random variable taking values in T, independent of X. Let  $\tau_t = \tau + t$  and let  $Y_t = (X_{\tau_t}, \tau_t)$  for  $t \in T$ . Then  $Y = \{Y_t : t \in T\}$  is a homogeneous Markov process with state space  $(S \times T, \mathscr{S} \otimes \mathscr{T})$ . For  $t \in T$ , the transition kernel  $P_t$  is given by

$$P_{t}[(x,r), A \times B] = \mathbb{P}(X_{r+t} \in A \mid X_{r} = x)\mathbf{1}(r+t \in B), \quad (x,r) \in S \times T, \ A \times B \in \mathscr{S} \otimes \mathscr{T}$$

$$(16.1.29)$$

Proof

By definition and the substitution rule,

$$egin{aligned} \mathbb{P}[Y_{s+t} \in A imes B \mid Y_s = (x,r)] &= \mathbb{P}\left(X_{ au_{s+t}} \in A, au_{s+t} \in B \mid X_{ au_s} = x, au_s = r
ight) \ &= \mathbb{P}\left(X_{ au_{s+t}} \in A, au + s + t \in B \mid X_{ au_{s+s}} = x, au + s = r
ight) \ &= \mathbb{P}(X_{r+t} \in A, r+t \in B \mid X_r = x, au + s = r) \end{aligned}$$

But  $\tau$  is independent of X, so the last term is

 $\mathbb{P}(X_{r+t} \in A, r+t \in B \mid X_r = x) = \mathbb{P}(X_{r+t} \in A \mid X_r = x)\mathbf{1}(r+t \in B)$ (16.1.30)

The important point is that the last expression does not depend on s, so Y is homogeneous.

The trick of enlarging the state space is a common one in the study of stochastic processes. Sometimes a process that has a weaker form of "forgetting the past" can be made into a Markov process by enlarging the state space appropriately. Here is an example in discrete time.

Suppose that  $X = \{X_n : n \in \mathbb{N}\}$  is a random process with state space  $(S, \mathscr{S})$  in which the future depends stochastically on the last two states. That is, for  $n \in \mathbb{N}$ 

$$\mathbb{P}(X_{n+2} \in A \mid \mathscr{F}_{n+1}) = \mathbb{P}(X_{n+2} \in A \mid X_n, X_{n+1}), \quad A \in \mathscr{S}$$

$$(16.1.31)$$

where  $\{\mathscr{P}_n : n \in \mathbb{N}\}$  is the natural filtration associated with the process X. Suppose also that the process is time homogeneous in the sense that

$$\mathbb{P}(X_{n+2} \in A \mid X_n = x, X_{n+1} = y) = Q(x, y, A) \tag{16.1.32}$$

independently of  $n \in \mathbb{N}$ . Let  $Y_n = (X_n, X_{n+1})$  for  $n \in \mathbb{N}$ . Then  $Y = \{Y_n : n \in \mathbb{N}\}$  is a homogeneous Markov process with state space  $(S \times S, S \otimes S)$ . The one step transition kernel P is given by

$$P[(x,y),A \times B] = I(y,A)Q(x,y,B); \quad x, y \in S, \ A, \ B \in \mathscr{S}$$

$$(16.1.33)$$

Proof

Note first that for  $n \in \mathbb{N}$ ,  $\sigma\{Y_k : k \le n\} = \sigma\{(X_k, X_{k+1}) : k \le n\} = \mathscr{F}_{n+1}$  so the natural filtration associated with the process Y is  $\{\mathscr{F}_{n+1} : n \in \mathbb{N}\}$ . If  $C \in \mathscr{S} \otimes \mathscr{S}$  then

$$\mathbb{P}(Y_{n+1} \in C \mid \mathscr{F}_{n+1}) = \mathbb{P}[(X_{n+1}, X_{n+2}) \in C \mid \mathscr{F}_{n+1}] \ = \mathbb{P}[(X_{n+1}, X_{n+2}) \in C \mid X_n, X_{n+1}] = \mathbb{P}(Y_{n+1} \in C \mid Y_n)$$

by the given assumption on  $\boldsymbol{X}$ . Hence  $\boldsymbol{Y}$  is a Markov process. Next,

$$\begin{split} \mathbb{P}[Y_{n+1} \in A \times B \mid Y_n = (x,y)] &= \mathbb{P}[(X_{n+1}, X_{n+2}) \in A \times B \mid (X_n, X_{n+1}) = (x,y)] \\ &= \mathbb{P}(X_{n+1} \in A, X_{n+2} \in B \mid X_n = x, X_{n+1} = y) = \mathbb{P}(y \in A, X_{n+2} \in B \mid X_n = x, X_{n+1} = y) \\ &= I(y,A)Q(x,y,B) \end{split}$$

The last result generalizes in a completely straightforward way to the case where the future of a random process in discrete time depends stochastically on the last k states, for some fixed  $k \in \mathbb{N}$ .

# **Examples and Applications**

#### **Recurrence Relations and Differential Equations**

As noted in the introduction, Markov processes can be viewed as stochastic counterparts of deterministic recurrence relations (discrete time) and differential equations (continuous time). Our goal in this discussion is to explore these connections.

Suppose that  $X = \{X_n : n \in \mathbb{N}\}$  is a stochastic process with state space  $(S, \mathscr{S})$  and that X satisfies the recurrence relation

$$X_{n+1} = g(X_n), \quad n \in \mathbb{N}$$
 (16.1.34)

where  $g: S \to S$  is measurable. Then X is a homogeneous Markov process with one-step transition operator P given by  $Pf = f \circ g$  for a measurable function  $f: S \to \mathbb{R}$ .

Proof

Clearly X is uniquely determined by the initial state, and in fact  $X_n = g^n(X_0)$  for  $n \in \mathbb{N}$  where  $g^n$  is the *n*-fold composition power of g. So the only possible source of randomness is in the initial state. The Markov and time homogeneous properties simply follow from the trivial fact that  $g^{m+n}(X_0) = g^n[g^m(X_0)]$ , so that  $X_{m+n} = g^n(X_m)$ . That is, the state at time m+n is completely determined by the state at time m (regardless of the previous states) and the time increment n. In particular,  $Pf(x) = \mathbb{E}[g(X_1) \mid X_0 = x] = f[g(x)]$  for measurable  $f: S \to \mathbb{R}$  and  $x \in S$ . Note that for  $n \in \mathbb{N}$ , the *n*-step transition operator is given by  $P^n f = f \circ g^n$ .

In the deterministic world, as in the stochastic world, the situation is more complicated in continuous time. Nonetheless, the same basic analogy applies.

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  with state space  $(\mathbb{R}, \mathscr{R})$  satisfies the first-order differential equation

$$\frac{d}{dt}X_t = g(X_t) \tag{16.1.35}$$

where  $g:\mathbb{R} \to \mathbb{R}$  is Lipschitz continuous. Then  $oldsymbol{X}$  is a Feller Markov process

Proof

Recall that *Lipschitz continuous* means that there exists a constant  $k \in (0, \infty)$  such that  $|g(y) - g(x)| \le k |x - y|$  for  $x, y \in \mathbb{R}$ . This is a standard condition on g that guarantees the existence and uniqueness of a solution to the differential equation on  $[0, \infty)$ . So as before, the only source of randomness in the process comes from the initial value  $X_0$ . Let  $t \mapsto X_t(x)$  denote the unique solution with  $X_0(x) = x$  for  $x \in \mathbb{R}$ . The Markov and homogenous properties follow from the fact that  $X_{t+s}(x) = X_t(X_s(x))$  for  $s, t \in [0, \infty)$  and  $x \in S$ . That is, the state at time t + s depends only on the state at time s and the time increment t. The Feller properties follow from the continuity of  $t \mapsto X_t(x)$  and the continuity of  $x \mapsto X_t(x)$ . The latter is the *continuous dependence on the initial value*, again guaranteed by the assumptions on g. Note that the transition operator is given by  $P_t f(x) = f[X_t(x)]$  for a measurable function  $f : S \to \mathbb{R}$  and  $x \in S$ .

In differential form, the process can be described by  $dX_t = g(X_t) dt$ . This essentially deterministic process can be extended to a very important class of Markov processes by the addition of a stochastic term related to Brownian motion. Such *stochastic differential equations* are the main tools for constructing Markov processes known as *diffusion processes*.

# Processes with Stationary, Independent Increments

For our next discussion, we consider a general class of stochastic processes that are Markov processes. Suppose that  $X = \{X_t : t \in T\}$  is a random process with  $S \subseteq \mathbb{R}$  as the set of states. The state space can be discrete (countable) or "continuous". Typically, S is either  $\mathbb{N}$  or  $\mathbb{Z}$  in the discrete case, and is either  $[0, \infty)$  or  $\mathbb{R}$  in the continuous case. In any case, S is given the usual  $\sigma$ -algebra  $\mathscr{S}$  of Borel subsets of S (which is the power set in the discrete case). Also, the state space  $(S, \mathscr{S})$  has a natural reference measure measure  $\lambda$ , namely counting measure in the discrete case and Lebesgue measure in the continuous case. Let  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$  denote the natural filtration, so that  $\mathscr{F}_t = \sigma\{X_s : s \in T, s \leq t\}$  for  $t \in T$ .

The process  $oldsymbol{X}$  has

1. *Independent increments* if  $X_{s+t} - X_s$  is independent of  $\mathscr{F}_s$  for all  $s, t \in T$ .

2. *Stationary increments* if the distribution of  $X_{s+t} - X_s$  is the same as the distribution of  $X_t - X_0$  for all  $s, t \in T$ .

A difference of the form  $X_{s+t} - X_s$  for  $s, t \in T$  is an *increment* of the process, hence the names. Sometimes the definition of stationary increments is that  $X_{s+t} - X_s$  have the same distribution as  $X_t$ . But this forces  $X_0 = 0$  with probability 1, and as usual with Markov processes, it's best to keep the initial distribution unspecified. If X has stationary increments in the sense of our definition, then the process  $Y = \{Y_t = X_t - X_0 : t \in T\}$  has stationary increments in the more restricted sense. For the remainder of this discussion, assume that  $X = \{X_t : t \in T\}$  has stationary, independent increments, and let  $Q_t$  denote the distribution of  $X_t - X_0$  for  $t \in T$ .

 $Q_s st Q_t = Q_{s+t} \; ext{ for } s, \; t \in T$  .

Proof

For  $s, t \in T$ ,  $Q_s$  is the distribution of  $X_s - X_0$ , and by the stationary property,  $Q_t$  is the distribution of  $X_{s+t} - X_s$ . By the independence property,  $X_s - X_0$  and  $X_{s+t} - X_s$  are independent. Hence  $Q_s * Q_t$  is the distribution of  $[X_s - X_0] + [X_{s+t} - X_s] = X_{s+t} - X_0$ . But by definition, this variable has distribution  $Q_{s+t}$ 

So the collection of distributions  $Q = \{Q_t : t \in T\}$  forms a semigroup, with convolution as the operator. Note that  $Q_0$  is simply point mass at 0.

The process X is a homogeneous Markov process. For  $t \in T$ , the transition operator  $P_t$  is given by

$$P_t f(x) = \int_S f(x+y)Q_t(dy), \quad f \in \mathscr{B}$$
(16.1.36)

Proof

Suppose that  $s,\,t\in T$  and  $f\in \mathscr{B}$  ,

 $\mathbb{E}[f(X_{s+t}) \mid \mathscr{F}_s] = \mathbb{E}[f(X_{s+t} - X_s + X_s) \mid \mathscr{F}_s] = \mathbb{E}[f(X_{s+t}) \mid X_s]$ (16.1.37)

since  $X_{s+t} - X_s$  is independent of  $\mathscr{F}_s$ . Moreover, by the stationary property,

$$\mathbb{E}[f(X_{s+t}) \mid X_s = x] = \int_S f(x+y)Q_t(dy), \quad x \in S$$
(16.1.38)

Clearly the semigroup property of  $\mathbf{P} = \{P_t : t \in T\}$  (with the usual operator product) is equivalent to the semigroup property of  $\mathbf{Q} = \{Q_t : t \in T\}$  (with convolution as the product).

Suppose that for positive  $t \in T$ , the distribution  $Q_t$  has probability density function  $g_t$  with respect to the reference measure  $\lambda$ . Then the transition *density* is

$$p_t(x,y) = g_t(y-x), \quad x, y \in S$$
 (16.1.39)

Of course, from the result above, it follows that  $g_s * g_t = g_{s+t}$  for  $s, t \in T$ , where here \* refers to the convolution operation on probability density functions.

If  $Q_t o Q_0$  as  $t \downarrow 0$  then  $oldsymbol{X}$  is a Feller Markov process.

Thus, by the general theory sketched above, **X** is a strong Markov process, and there exists a version of **X** that is right continuous and has left limits. Such a process is known as a *Lévy process*, in honor of Paul Lévy.

For a real-valued stochastic process  $m{X} = \{X_t: t \in T\}$  , let m and v denote the mean and variance functions, so that

$$h(t) = \mathbb{E}(X_t), \ v(t) = \operatorname{var}(X_t); \quad t \in T$$
(16.1.40)

assuming of course that the these exist. The mean and variance functions for a Lévy process are particularly simple.

Suppose again that  $\boldsymbol{X}$  has stationary, independent increments.

1. If  $\mu_0 = \mathbb{E}(X_0) \in \mathbb{R}$  and  $\mu_1 = \mathbb{E}(X_1) \in \mathbb{R}$  then  $m(t) = \mu_0 + (\mu_1 - \mu_0)t$  for  $t \in T$ .

2. If in addition,  $\sigma_0^2 = \operatorname{var}(X_0) \in (0, \infty)$  and  $\sigma_1^2 = \operatorname{var}(X_1) \in (0, \infty)$  then  $v(t) = \sigma_0^2 + (\sigma_1^2 - \sigma_0^2)t$  for  $t \in T$ .

Proof

The proofs are simple using the independent and stationary increments properties. For  $t \in T$ , let  $m_0(t) = \mathbb{E}(X_t - X_0) = m(t) - \mu_0$  and  $v_0(t) = \operatorname{var}(X_t - X_0) = v(t) - \sigma_0^2$ . denote the mean and variance functions for the centered process  $\{X_t - X_0 : t \in T\}$ . Now let  $s, t \in T$ .

1. From the additive property of expected value and the stationary property,

$$m_0(t+s) = \mathbb{E}(X_{t+s} - X_0) = \mathbb{E}[(X_{t+s} - X_s) + (X_s - X_0)] = \mathbb{E}(X_{t+s} - X_s) + \mathbb{E}(X_s - X_0) = m_0(t) + m_0(s)$$
(16.1.41)

2. From the additive property of variance for independent variables and the stationary property,

$$v_0(t+s) = \operatorname{var}(X_{t+s} - X_0) = \operatorname{var}[(X_{t+s} - X_s) + (X_s - X_0)] = \operatorname{var}(X_{t+s} - X_s) + \operatorname{var}(X_s - X_0) = v_0(t) + v_0(s) \quad (16.1.42)$$

So  $m_0$  and  $v_0$  satisfy the *Cauchy equation*. In discrete time, it's simple to see that there exists  $a \in \mathbb{R}$  and  $b^2 \in (0, \infty)$  such that  $m_0(t) = at$  and  $v_0(t) = b^2 t$ . The same is true in continuous time, given the continuity assumptions that we have on the process  $\mathbf{X}$ . Substituting t = 1 we have  $a = \mu_1 - \mu_0$  and  $b^2 = \sigma_1^2 - \sigma_0^2$ , so the results follow,

It's easy to describe processes with stationary independent increments in discrete time.

A process  $X = \{X_n : n \in \mathbb{N}\}$  has independent increments if and only if there exists a sequence of independent, real-valued random variables  $(U_0, U_1, \ldots)$  such that

$$X_n = \sum_{i=0}^n U_i$$
 (16.1.43)

In addition, X has stationary increments if and only if  $(U_1, U_2, ...)$  are identically distributed.

Proof

Suppose first that  $U = (U_0, U_1, ...)$  is a sequence of independent, real-valued random variables, and define  $X_n = \sum_{i=0}^n U_i$  for  $n \in \mathbb{N}$ . Note that  $\mathscr{F}_n = \sigma\{X_0, ..., X_n\} = \sigma\{U_0, ..., U_n\}$  for  $n \in \mathbb{N}$ . If  $k, n \in \mathbb{N}$  with  $k \leq n$ , then  $X_n - X_k = \sum_{i=k+1}^n U_i$  which is independent of  $\mathscr{F}_k$  by the independence assumption on U. Hence X has independent suppose in addition that  $(U_1, U_2, ...)$  are identically distributed. Then the increment  $X_n - X_k$  above has the same distribution as  $\sum_{i=1}^{n-k} U_i = X_{n-k} - X_0$ . Hence X has stationary increments.

Conversely, suppose that  $\mathbf{X} = \{X_n : n \in \mathbb{N}\}$  has independent increments. Let  $U_0 = X_0$  and  $U_n = X_n - X_{n-1}$  for  $n \in \mathbb{N}_+$ . Then  $X_n = \sum_{i=0}^n U_i$  for  $n \in \mathbb{N}$ . As before  $\mathscr{P}_n = \sigma\{X_0, \dots, X_n\} = \sigma\{U_0, \dots, U_n\}$  for  $n \in \mathbb{N}$ . Since  $\mathbf{X}$  has independent increments,  $U_n$  is independent of  $\mathscr{P}_{n-1}$  for  $n \in \mathbb{N}_+$ , so  $(U_0, U_1, \dots)$  are mutually independent. If in addition,  $\mathbf{X}$  has stationary increments,  $U_n = X_n - X_{n-1}$  has the same distribution as  $X_1 - X_0 = U_1$  for  $n \in \mathbb{N}_+$ . Hence  $(U_1, U_2, \dots)$  are identically distributed.

Thus suppose that  $U = (U_0, U_1, ...)$  is a sequence of independent, real-valued random variables, with  $(U_1, U_2, ...)$  identically distributed with common distribution Q. Then from our main result above, the partial sum process  $X = \{X_n : n \in \mathbb{N}\}$  associated with U is a homogeneous Markov process with one step transition kernel P given by

$$P(x,A) = Q(A-x), \quad x \in S, \ A \in \mathscr{S}$$
 (16.1.44)

More generally, for  $n \in \mathbb{N}$ , the *n*-step transition kernel is  $P^n(x, A) = Q^{*n}(A - x)$  for  $x \in S$  and  $A \in \mathscr{S}$ . This Markov process is known as a *random walk* (although unfortunately, the term *random walk* is used in a number of other contexts as well). The idea is that at time *n*, the walker moves a (directed) distance  $U_n$  on the real line, and these steps are independent and identically distributed. If *Q* has probability density function *g* with respect to the reference measure  $\lambda$ , then the one-step transition density is

$$p(x,y) = g(y-x), \quad x, y \in S$$
 (16.1.45)

Consider the random walk on  $\mathbb{R}$  with steps that have the standard normal distribution. Give each of the following explicitly:

1

1. The one-step transition density.

2. The *n*-step transition density for  $n \in \mathbb{N}_+$  .

Proof

1. For  $x \in \mathbb{R}$  ,  $p(x, \cdot)$  is the normal PDF with mean x and variance 1:

$$p(x,y) = rac{1}{\sqrt{2\pi}} \exp \left[ -rac{1}{2} (y-x)^2 
ight]; \quad x, \, y \in \mathbb{R}$$
 (16.1.46)

2. For  $x \in \mathbb{R}$  ,  $p^n(x, \cdot)$  is the normal PDF with mean x and variance n:

$$p^{n}(x,y) = rac{1}{\sqrt{2\pi n}} \exp\left[-rac{1}{2n}(y-x)^{2}
ight], \quad x, y \in \mathbb{R}$$
 (16.1.47)

In continuous time, there are two processes that are particularly important, one with the discrete state space  $\mathbb{N}$  and one with the continuous state space  $\mathbb{R}$ .

For  $t \in [0, \infty)$ , let  $g_t$  denote the probability density function of the Poisson distribution with parameter t, and let  $p_t(x, y) = g_t(y - x)$  for  $x, y \in \mathbb{N}$ . Then  $\{p_t : t \in [0, \infty)\}$  is the collection of transition densities for a Feller semigroup on  $\mathbb{N}$ 

Proof

Recall that

$$g_t(n) = e^{-t} rac{t^n}{n!}, \quad n \in \mathbb{N}$$
 (16.1.48)

We just need to show that  $\{g_t : t \in [0, \infty)\}$  satisfies the semigroup property, and that the continuity result holds. But we already know that if U, V are independent variables having Poisson distributions with parameters  $s, t \in [0, \infty)$ , respectively, then U + V has the Poisson distribution with parameter s + t. That is,  $g_s * g_t = g_{s+t}$ . Moreover,  $g_t \to g_0$  as  $t \downarrow 0$ .

So a Lévy process  $N = \{N_t : t \in [0, \infty)\}$  with these transition densities would be a Markov process with stationary, independent increments and with sample paths are right continuous and have left limits. We do know of such a process, namely the Poisson process with rate 1.

Open the Poisson experiment and set the rate parameter to 1 and the time parameter to 10. Run the experiment several times in single-step mode and note the behavior of the process.

For  $t \in (0, \infty)$ , let  $g_t$  denote the probability density function of the normal distribution with mean 0 and variance t, and let  $p_t(x, y) = g_t(y - x)$  for  $x, y \in \mathbb{R}$ . Then  $\{p_t : t \in [0, \infty)\}$  is the collection of transition densities of a Feller semigroup on  $\mathbb{R}$ .

Proof

Recall that for  $t \in (0, \infty)$ ,

$$g_t(z) = rac{1}{\sqrt{2\pi t}} \exp\left(-rac{z^2}{2t}
ight), \quad z \in \mathbb{R}$$
 (16.1.49)

We just need to show that  $\{g_t : t \in [0, \infty)\}$  satisfies the semigroup property, and that the continuity result holds. But we already know that if U, V are independent variables having normal distributions with mean 0 and variances  $s, t \in (0, \infty)$ , respectively, then U+V has the normal distribution with mean 0 and variance s+t. That is,  $g_s * g_t = g_{s+t}$ . Moreover, we also know that the normal distribution with variance t converges to point mass at 0 as  $t \downarrow 0$ .

So a Lévy process  $X = \{X_t : t \in [0, \infty)\}$  on  $\mathbb{R}$  with these transition densities would be a Markov process with stationary, independent increments, and whose sample paths are continuous from the right and have left limits. In fact, there exists such a process with *continuous* sample paths. This process is Brownian motion, a process important enough to have its own chapter.

Run the simulation of standard Brownian motion and note the behavior of the process.

# 16.2: Potentials and Generators for General Markov Processes

Our goal in this section is to continue the broad sketch of the general theory of Markov processes. As with the last section, some of the statements are not completely precise and rigorous, because we want to focus on the main ideas without being overly burdened by technicalities. If you are a new student of probability, or are primarily interested in applications, you may want to skip ahead to the study of discrete-time Markov chains.

# **Preliminaries**

#### **Basic Definitions**

As usual, our starting point is a probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ , so that  $\Omega$  is the set of outcomes,  $\mathscr{F}$  the  $\sigma$ -algebra of events, and  $\mathbb{P}$  the probability measure on the sample space  $(\Omega, \mathscr{F})$ . The set of times T is either  $\mathbb{N}$ , discrete time with the discrete topology, or  $[0, \infty)$ , continuous time with the usual Euclidean topology. The time set T is given the Borel  $\sigma$ -algebra  $\mathscr{F}$ , which is just the power set if  $T = \mathbb{N}$ , and then the time space  $(T, \mathscr{F})$  is given the usual measure, counting measure in the discrete case and Lebesgue measure in the continuous case. The set of states S has an LCCB topology (locally compact, Hausdorff, with a countable base), and is also given the Borel  $\sigma$ -algebra  $\mathscr{F}$ . Recall that to say that the state space is *discrete* means that S is countable with the discrete topology, so that  $\mathscr{F}$  is the power set of S. The topological assumptions mean that the state space  $(S, \mathscr{F})$  is nice enough for a rich mathematical theory and general enough to encompass the most important applications. There is often a natural Borel measure  $\lambda$  on  $(S, \mathscr{F})$ , counting measure # if S is discrete, and for example, Lebesgue measure if  $S = \mathbb{R}^k$  for some  $k \in \mathbb{N}_+$ .

Recall also that there are several spaces of functions on S that are important. Let  $\mathscr{B}$  denote the set of bounded, measurable functions  $f: S \to \mathbb{R}$ . Let  $\mathscr{C}$  denote the set of bounded, continuous functions  $f: S \to \mathbb{R}$ , and let  $\mathscr{C}_0$  denote the set of continuous functions  $f: S \to \mathbb{R}$  that vanish at  $\infty$  in the sense that for every  $\epsilon > 0$ , there exists a compact set  $K \subseteq S$  such  $|f(x)| < \epsilon$  for  $x \in K^c$ . These are all vector spaces under the usual (pointwise) addition and scalar multiplication, and  $\mathscr{C}_0 \subseteq \mathscr{C} \subseteq \mathscr{B}$ . The supremum norm, defined by  $||f|| = \sup\{|f(x)| : x \in S\}$  for  $f \in \mathscr{B}$  is the norm that is used on these spaces.

Suppose now that  $X = \{X_t : t \in T\}$  is a time-homogeneous Markov process with state space  $(S, \mathscr{S})$  defined on the probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ . As before, we also assume that we have a *filtration*  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$ , that is, an increasing family of sub  $\sigma$ -algebras of  $\mathscr{F}$ , indexed by the time space, with the properties that  $X_t$  is measurable with repsect to  $\mathscr{F}_t$  for  $t \in T$ . Intuitively,  $\mathscr{F}_t$  is the collection of events up to time  $t \in T$ .

As usual, we let  $P_t$  denote the transition probability kernel for an increase in time of size  $t \in T$ . Thus

$$P_t(x,A) = \mathbb{P}(X_t \in A \mid X_0 = x), \quad x \in S, A \in \mathscr{S}$$

$$(16.2.1)$$

Recall that for  $t \in T$ , the transition kernel  $P_t$  defines two operators, on the *left* with measures and on the *right* with functions. So, if  $\mu$  is a measure on  $(S, \mathscr{S})$  then  $\mu P_t$  is the measure on  $(S, \mathscr{S})$  given by

$$\mu P_t(A) = \int_S \mu(dx) P_t(x, A), \quad A \in \mathscr{S}$$
(16.2.2)

If  $\mu$  is the distribution of  $X_0$  then  $\mu P_t$  is the distribution of  $X_t$  for  $t \in T$ . If  $f \in \mathscr{B}$  then  $P_t f \in \mathscr{B}$  is defined by

$$P_t f(x) = \int_S P_t(x, dy) f(y) = \mathbb{E} \left[ f(X_t) \mid X_0 = x \right]$$
(16.2.3)

Recall that the collection of transition operators  $P = \{P_t : t \in T\}$  is a semigroup because  $P_sP_t = P_{s+t}$  for  $s, t \in T$ . Just about everything in this section is defined in terms of the semigroup P, which is one of the main analytic tools in the study of Markov processes.

#### Feller Markov Processes

We make the same assumptions as in the Introduction. Here is a brief review:

We assume that the Markov process  $X = \{X_t : t \in T\}$  satisfies the following properties (and hence is a *Feller* Markov process):

- 1. For  $t \in T$  and  $y \in S$ , the distribution of  $X_t$  given  $X_0 = x$  converges to the distribution of  $X_t$  given  $X_0 = y$  as  $x \to y$ .
- 2. Given  $X_0 = x \in S$  ,  $X_t$  converges in probability to x as  $t \downarrow 0$  .

Part (a) is an assumption on *continuity in space*, while part (b) is an assumption on *continuity in time*. If S is discrete then (a) automatically holds, and if T is discrete then (b) automatically holds. As we will see, the Feller assumptions are sufficient for a very nice mathematical theory, and yet are general enough to encompass the most important continuous-time Markov processes.

The process  $\boldsymbol{X} = \{X_t : t \in T\}$  has the following properties:

- 1. There is a version of  $\boldsymbol{X}$  such that  $t \mapsto X_t$  is continuous from the right and has left limits.
- 2. **X** is a strong Markov process relative to the  $\mathfrak{F}^0_+$ , the right-continuous refinement of the natural filtration.

The Feller assumptions on the Markov process have equivalent formulations in terms of the transition semigroup.

The transition semigroup  $oldsymbol{P}=\{P_t:t\in T\}\$ has the following properties:

1. If  $f \in \mathscr{C}_0$  and  $t \in T$  then  $P_t f \in \mathscr{C}_0$ 2. If  $f \in \mathscr{C}_0$  and  $x \in S$  then  $P_t f(x) \to f(x)$  as  $t \downarrow 0$ .

As before, part (a) is a condition on *continuity in space*, while part (b) is a condition on *continuity in time*. Once again, (a) is trivial if S is discrete, and (b) trivial if T is discrete. The first condition means that  $P_t$  is a linear operator on  $\mathscr{C}_0$  (as well as being a linear operator on  $\mathscr{B}$ ). The second condition leads to a stronger continuity result.

For  $f \in \mathscr{C}_0$ , the mapping  $t \mapsto P_t f$  is continuous on T. That is, for  $t \in T$ ,  $\|P_s f - P_t f\| = \sup\{|P_s f(x) - P_t f(x)| : x \in S\} \to 0 \text{ as } s \to t$  (16.2.4)

Our interest in this section is primarily the continuous time case. However, we start with the discrete time case since the concepts are clearer and simpler, and we can avoid some of the technicalities that inevitably occur in continuous time.

# **Discrete Time**

Suppose that  $T = \mathbb{N}$ , so that time is discrete. Recall that the transition kernels are just powers of the one-step kernel. That is, we let  $P = P_1$  and then  $P_n = P^n$  for  $n \in \mathbb{N}$ .

# **Potential Operators**

For  $\alpha \in (0, 1]$ , the  $\alpha$ -potential kernel  $R_{\alpha}$  of  $\boldsymbol{X}$  is defined as follows:

$$R_{\alpha}(x,A) = \sum_{n=0}^{\infty} \alpha^{n} P^{n}(x,A), \quad x \in S, A \in \mathscr{S}$$
(16.2.5)

1. The special case  $R = R_1$  is simply the *potential kernel* of **X**.

2. For  $x \in S$  and  $A \in \mathscr{S}$ , R(x, A) is the expected number of visits of X to A, starting at x.

Proof

The function  $x \mapsto R_{\alpha}(x, A)$  from S to  $[0, \infty)$  is measurable for  $A \in \mathscr{S}$  since  $x \mapsto P^n(x, A)$  is measurable for each  $n \in \mathbb{N}$ . The mapping  $A \mapsto R_{\alpha}(x, A)$  is a positive measure on  $\mathscr{S}$  for  $x \in S$  since  $A \mapsto P^n(x, A)$  is a probability measure for each  $n \in \mathbb{N}$ . Finally, the interpretation of R(x, A) for  $x \in S$  and  $A \in \mathscr{S}$  comes from interchanging sum and expected value, which is allowed since the terms are nonnegative:

$$R(x,A) = \sum_{n=0}^{\infty} P^n(x,A) = \sum_{n=0}^{\infty} \mathbb{E}[\mathbf{1}(X_n \in A) \mid X_0 = x] = \mathbb{E}\left(\sum_{n=0}^{\infty} \mathbf{1}(X_n \in A) \mid X_0 = x\right) = \mathbb{E}[\#\{n \in \mathbb{N} : X_n \in A\} \mid X_0 = x] \quad (16.2.6)$$

Note that it's quite possible that  $R(x, A) = \infty$  for some  $x \in S$  and  $A \in S$ . In fact, knowing when this is the case is of considerable importance in the study of Markov processes. As with all kernels, the potential kernel  $R_{\alpha}$  defines two operators, operating on the right on functions, and operating on the left on positive measures. For the right potential operator, if  $f : S \to \mathbb{R}$  is measurable then

$$R_{\alpha}f(x) = \sum_{n=0}^{\infty} \alpha^{n} P^{n}f(x) = \sum_{n=0}^{\infty} \alpha^{n} \int_{S} P^{n}(x, dy)f(y) = \sum_{n=0}^{\infty} \alpha^{n} \mathbb{E}[f(X_{n}) \mid X_{0} = x], \quad x \in S$$
(16.2.7)

assuming as usual that the expected values and the infinite series make sense. This will be the case, in particular, if f is nonnegative or if  $p \in (0, 1)$  and  $f \in \mathscr{B}$ .

If 
$$\alpha \in (0,1)$$
, then  $R_{\alpha}(x,S) = \frac{1}{1-\alpha}$  for all  $x \in S$ 

Proof

Using geometric series,

$$R_{\alpha}(x,S) = \sum_{n=0}^{\infty} \alpha^{n} P^{n}(x,S) = \sum_{n=0}^{\infty} \alpha^{n} = \frac{1}{1-\alpha}$$
(16.2.8)

It follows that for  $\alpha \in (0, 1)$ , the right operator  $R_{\alpha}$  is a bounded, linear operator on  $\mathscr{B}$  with  $||R_{\alpha}|| = \frac{1}{1-\alpha}$ . It also follows that  $(1-\alpha)R_{\alpha}$  is a probability kernel. There is a nice interpretation of this kernel.

If  $\alpha \in (0, 1)$  then  $(1 - \alpha)R_{\alpha}(x, \cdot)$  is the conditional distribution of  $X_N$  given  $X_0 = x \in S$ , where N is independent of X and has the geometric distribution on  $\mathbb{N}$  with parameter  $1 - \alpha$ .

Proof

Suppose that  $x \in S$  and  $A \in \mathscr{S}$ . Conditioning on N gives

$$\mathbb{P}(X_N \in A \mid X_0 = x) = \sum_{n=0}^{\infty} \mathbb{P}(N = n) \mathbb{P}(X_N \in A \mid N = n, X_0 = x)$$
(16.2.9)

But by the substitution rule and the assumption of independence,

$$\mathbb{P}(X_N \in A \mid N = n, X_0 = x) = \mathbb{P}(X_n \in A \mid N = n, X_0 = x) = \mathbb{P}(X_n \in A \mid X_0 = x) = P^n(x, A)$$
(16.2.10)

Since N has the geometric distribution on N with parameter  $1 - \alpha$  we have  $P(N = n) = (1 - \alpha)\alpha^n$  for  $n \in \mathbb{N}$ . Substituting gives

$$\mathbb{P}(X_N \in A \mid X_0 = x) = \sum_{n=0}^{\infty} (1 - \alpha) \alpha^n P^n(x, A) = (1 - \alpha) R_\alpha(x, A)$$
(16.2.11)

So  $(1-\alpha)R_{\alpha}$  is a transition probability kernel, just as  $P_n$  is a transition probability kernel, but corresponding to the *random* time N (with  $\alpha \in (0, 1)$  as a parameter), rather than the *deterministic* time  $n \in \mathbb{N}$ . An interpretation of the potential kernel  $R_{\alpha}$  for  $\alpha \in (0, 1)$  can be also given in economic terms. Suppose that  $A \in \mathscr{S}$  and that we receive one monetary unit each time the process X visits A. Then as above, R(x, A) is the expected total amount of money we receive, starting at  $x \in S$ . However, typically money that we will receive at times distant in the future has less value to us *now* than money that we will receive soon. Specifically suppose that a monetary unit received at time  $n \in \mathbb{N}$  has a *present value* of  $\alpha^n$ , where  $\alpha \in (0, 1)$  is an *inflation factor* (sometimes also called a *discount factor*). Then  $R_{\alpha}(x, A)$  gives the expected, total, discounted amount we will receive when we visit state  $x \in S$ , then for  $\alpha \in (0, 1), R_{\alpha}f(x)$  is the expected, total, discounted reward, starting at  $x \in S$ .

For the left potential operator, if  $\mu$  is a positive measure on  ${\mathscr S}$  then

$$\mu R_{\alpha}(A) = \sum_{n=0}^{\infty} \alpha^n \mu P^n(A) = \sum_{n=0}^{\infty} \alpha^n \int_S \mu(dx) P^n(x, A), \quad A \in \mathscr{S}$$
(16.2.12)

In particular, if  $\mu$  is a probability measure and  $X_0$  has distribution  $\mu$  then  $\mu P^n$  is the distribution of  $X_n$  for  $n \in \mathbb{N}$ , so from the last result,  $(1 - \alpha)\mu R_\alpha$  is the distribution of  $X_N$  where again, N is independent of  $\boldsymbol{X}$  and has the geometric distribution on  $\mathbb{N}$  with parameter  $1 - \alpha$ . The family of potential kernels gives the same information as the family of transition kernels.

The potential kernels  $\mathbf{R} = \{R_{\alpha} : \alpha \in (0, 1)\}$  completely determine the transition kernels  $\mathbf{P} = \{P_n : n \in \mathbb{N}\}$ .

Proof

Note that for  $x \in S$  and  $A \in \mathscr{S}$ , the function  $\alpha \mapsto R_{\alpha}(x, A)$  is a power series in  $\alpha$  with coefficients  $n \mapsto P^n(x, A)$ . In the language of combinatorics,  $\alpha \mapsto R_{\alpha}(x, A)$  is the *ordinary generating function* of the sequence  $n \mapsto P^n(x, A)$ . As noted above, this power series has radius of convergence at least 1, so we can extend the domain to  $\alpha \in (-1, 1)$ . Thus, given the potential kernels, we can recover the transition kernels by taking derivatives and evaluating at 0:

$$P^{n}(x,A) = \frac{1}{n!} \left[ \frac{d^{n}}{d\alpha^{n}} R_{\alpha}(x,A) \right]_{\alpha=0}$$
(16.2.13)

Of course, it's really only necessary to determine *P*, the one step transition kernel, since the other transition kernels are powers of *P*. In any event, it follows that the kernels  $\mathbf{R} = \{R_{\alpha} : \alpha \in (0, 1)\}$ , along with the initial distribution, completely determine the finite dimensional distributions of the Markov process  $\mathbf{X}$ . The potential kernels commute with each other and with the transition kernels.

Suppose that  $\alpha$ ,  $\beta \in (0, 1]$  and  $k \in \mathbb{N}$ . Then (as kernels)

1. 
$$P^k R_{\alpha} = R_{\alpha} P^k = \sum_{n=0}^{\infty} \alpha^n P^{n+k}$$
  
2.  $R_{\alpha} R_{\beta} = R_{\beta} R_{\alpha} = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \alpha^m \beta^n P^{m+n}$   
Proof

Suppose that  $f \in \mathscr{B}$  is nonnegative. The interchange of the sums with the kernel operation is allowed since the kernels are nonnegative. The other tool used is the semigroup property.

1. Directly

$$R_{\alpha}P^{k}f = \sum_{n=0}^{\infty} \alpha^{n}P^{n}P^{k}f = \sum_{n=0}^{\infty} \alpha^{n}P^{n+k}f$$
(16.2.14)

The other direction requires an interchange.

$$P^{k}R_{\alpha}f = P^{k}\sum_{n=0}^{\infty}\alpha^{n}P^{n}f = \sum_{n=0}^{\infty}\alpha^{n}P^{k}P^{n}f = \sum_{n=0}^{\infty}\alpha^{n}P^{n+k}f$$
(16.2.15)

2. First,

$$R_{\alpha}R_{\beta}f = \sum_{m=0}^{\infty} \alpha^m P^m R_{\beta}f = \sum_{m=0}^{\infty} \alpha^m P^m \left(\sum_{n=0}^{\infty} \beta^n P^n f\right) = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \alpha^m \beta^n P^m P^n f = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \alpha^m \beta^n P^{m+n} f$$
(16.2.16)

The other direction is similar.

The same identities hold for the right operators on the entire space  $\mathscr{B}$ , with the additional restrictions that  $\alpha < 1$  and  $\beta < 1$ . The fundamental equation that relates the potential kernels is given next.

If 
$$lpha,\ eta\in(0,1]$$
 with  $lpha\leqeta$  then (as kernels),

$$\beta R_{\beta} = \alpha R_{\alpha} + (\beta - \alpha) R_{\alpha} R_{\beta} \tag{16.2.17}$$

# Proof

If  $\alpha = \beta$  the equation is trivial, so assume  $\alpha < \beta$ . Suppose that  $f \in \mathscr{B}$  is nonnegative. From the previous result,

$$R_{\alpha}R_{\beta}f = \sum_{j=0}^{\infty}\sum_{k=0}^{\infty}\alpha^{j}\beta^{k}P^{j+k}f$$
(16.2.18)

Changing variables to sum over n = j + k and j gives

$$R_{\alpha}R_{\beta}f = \sum_{n=0}^{\infty}\sum_{j=0}^{n}\alpha^{j}\beta^{n-j}P^{n}f = \sum_{n=0}^{\infty}\sum_{j=0}^{n}\left(\frac{\alpha}{\beta}\right)^{j}\beta^{n}P^{n}f = \sum_{n=0}^{\infty}\frac{1-\left(\frac{\alpha}{\beta}\right)^{n+j}}{1-\frac{\alpha}{\beta}}\beta^{n}P^{n}f$$
(16.2.19)

Simplifying gives

$$R_{\alpha}R_{\beta}f = \frac{1}{\beta - \alpha}(\beta R_{\beta}f - \alpha R_{\alpha}f)$$
(16.2.20)

Note that since  $\alpha < 1$ ,  $R_{\alpha}f$  is a finite, so we don't have to worry about the dreaded indeterminate form  $\infty - \infty$ .

The same identity holds holds for the right operators on the entire space  $\mathscr{B}$ , with the additional restriction that  $\beta < 1$ .

If  $lpha\in(0,1]$ , then (as kernels),  $I+lpha R_lpha P=I+lpha PR_lpha=R_lpha$  .

Proof

Suppose that  $f\in \mathscr{B}$  is nonnegative. From the result above,

$$(I + \alpha R_{\alpha}P)f = (I + \alpha PR_{\alpha})f = f + \sum_{n=0}^{\infty} \alpha^{n+1}P^{n+1}f = \sum_{n=0}^{\infty} \alpha^n P^n f = R_{\alpha}f$$
(16.2.21)

The same identity holds for the right operators on the entire space  $\mathcal{B}$ , with the additional restriction that  $\alpha < 1$ . This leads to the following important result:

If  $\alpha \in (0, 1)$ , then as operators on the space  $\mathscr{B}$ ,

1.  $R_{\alpha} = (I - \alpha P)^{-1}$ 2.  $P = \frac{1}{\alpha} (I - R_{\alpha}^{-1})$ 

Proof

The operators are bounded, so we can subtract. The identity  $I + \alpha R_{\alpha}P = R_{\alpha}$  leads to  $R_{\alpha}(I - \alpha P) = I$  and the identity  $I + \alpha PR_{\alpha} = R_{\alpha}$  leads to  $(I - \alpha P)R_{\alpha} = I$ . Hence (a) holds. Part (b) follows from (a).

This result shows again that the potential operator  $R_{\alpha}$  determines the transition operator P.

# Examples and Applications

Our first example considers the binomial process as a Markov process.

Let  $I = \{I_n : n \in \mathbb{N}_+\}$  be a sequence of Bernoulli trials with success parameter  $p \in (0, 1)$ . Define the Markov process  $X = \{X_n : n \in \mathbb{N}\}$  by  $X_n = X_0 + \sum_{k=1}^n I_k$  where  $X_0$  takes values in  $\mathbb{N}$  and is independent of I.

1. For  $n \in \mathbb{N}$ , show that the transition probability matrix  $P^n$  of  $\boldsymbol{X}$  is given by

$$P^n(x,y) = {n \choose y-x} p^{y-x} (1-p)^{n-y+x}, \quad x \in \mathbb{N}, \ y \in \{x,x+1,\dots,x+n\}$$
 (16.2.22)

2. For  $\alpha \in (0, 1]$ , show that the potential matrix  $R_{\alpha}$  of  $\boldsymbol{X}$  is given by

$$R_{lpha}(x,y)=rac{1}{1-lpha+lpha p}\left(rac{lpha p}{1-lpha+lpha p}
ight)^{y-x}, \quad x\in\mathbb{N},\,y\in\{x,x+1,\ldots\}$$
 $(16.2.23)$ 

3. For  $\alpha \in (0, 1)$  and  $x \in \mathbb{N}$ , identify the probability distribution defined by  $(1 - \alpha)R_{\alpha}(x, \cdot)$ . 4. For  $x, y \in \mathbb{N}$  with  $x \leq y$ , interpret R(x, y), the expected time in y starting in x, in the context of the process X.

Solutions

Recall that X is a Markov process since it has stationary, independent increments.

- 1. Note that for  $n, x \in \mathbb{N}$ ,  $P^n(x, \cdot)$  is the (discrete) PDF of  $x + \sum_{k=1}^n I_k$ . The result follows since the sum of the indicator variables has the binomial distribution with parameters n and p.
- 2. Let  $lpha \in (0,1]$  and let  $x, \, y \in \mathbb{N}$  with  $x \leq y$  . Then

$$\begin{aligned} R_{\alpha}(x,y) &= \sum_{n=0}^{\infty} \alpha^{n} P^{n}(x,y) = \sum_{n=y-x}^{\infty} \alpha^{n} \binom{n}{y-x} p^{y-x} (1-p)^{n-y+x} \\ &= (\alpha p)^{y-x} \sum_{n=y-x}^{\infty} \binom{n}{y-x} [\alpha (1-p)]^{n-y+x} = \frac{(\alpha p)^{y-x}}{[1-\alpha (1-p)]^{n-x+1}} \end{aligned}$$

Simplifying gives the result. 3. For  $lpha \in (0,1)$ ,

$$(1-\alpha)R_{\alpha}(x,y) = \frac{1-\alpha}{1-\alpha+\alpha p} \left(\frac{\alpha p}{1-\alpha+\alpha p}\right)^{y-x}$$
(16.2.24)

As a function of y for fixed x, this is the PDF of  $x + Y_{\alpha}$  where  $Y_{\alpha}$  has the geometric distribution on N with parameter  $\frac{1-\alpha}{1-\alpha+\alpha p}$ .

4. Note that R(x, y) = 1/p for  $x, y \in \mathbb{N}$  with  $x \leq y$ . Starting in state x, the process eventually reaches y with probability 1. The process remains in state y for a geometrically distributed time, with parameter p. The mean of this distribution is 1/p.

# **Continuous Time**

With the discrete-time setting as motivation, we now turn the more important continuous-time case where  $T = [0, \infty)$ .

# **Potential Kernels**

For  $\alpha \in [0, \infty)$ , the  $\alpha$ -potential kernel  $U_{\alpha}$  of  $\boldsymbol{X}$  is defined as follows:

$$U_{\alpha}(x,A) = \int_{0}^{\infty} e^{-\alpha t} P_{t}(x,A) dt, \quad x \in S, \ A \in \mathscr{S}$$

$$(16.2.25)$$

1. The special case  $U = U_0$  is simply the *potential kerenl* of **X**.

2. For  $x \in S$  and  $A \in \mathscr{S}$ , U(x, A) is the expected amount of time that **X** spends in A, starting at x.

3. The family of kernels  $U = \{U_{\alpha} : \alpha \in (0, \infty)\}$  is known as the *reolvent* of X.

Proof

Since  $P = \{P_t : t \in T\}$  is a Feller semigroup of transition operators, the mapping  $(t, x) \mapsto P_t(x, A)$  from  $[0, \infty) \times S$  to [0, 1] is jointly measurable for  $A \in \mathscr{S}$ . Thus,  $U_{\alpha}(x, A)$  makes sense for  $x \in S$  and  $A \in \mathscr{S}$  and  $x \mapsto U_{\alpha}(x, A)$  from S to  $[0, \infty)$  is measurable for  $A \in \mathscr{S}$ . That  $A \mapsto U_{\alpha}(x, A)$  is a measure on  $\mathscr{S}$  follows from the usual interchange of sum and integral, via Fubini's theorem: Suppose that  $\{A_j : j \in J\}$  is a countable collection of disjoint sets in  $\mathscr{S}$ , and let  $S = \bigcup_{j \in J} A_j$ 

$$egin{aligned} U_lpha(x,A) &= \int_0^\infty e^{-lpha t} P_t(x,A) \, dt = \int_0^\infty \left[ \sum_{j\in J} e^{-lpha t} P_t(x,A_j) 
ight] \, dt \ &= \sum_{j\in J} \int_0^\infty e^{-lpha t} P_t(x,A_j) \, dt = \sum_{j\in J} U_lpha(x,A_j) \end{aligned}$$

Finally, the interpretation of U(x, A) for  $x \in S$  and  $A \in \mathscr{S}$  is another interchange of integrals:

$$U(x,A) = \int_0^\infty P_t(x,A) \, dt = \int_0^\infty \mathbb{E}[\mathbf{1}(X_t \in A) \mid X_0 = x] \, dt = \mathbb{E}\left(\int_0^\infty \mathbf{1}(X_t \in A) \, dt \mid X_0 = x\right) \tag{16.2.26}$$

The inside integral is the Lebesgue measure of  $\{t \in [0,\infty) : X_t \in A\}$ .

As with discrete time, it's quite possible that  $U(x, A) = \infty$  for some  $x \in S$  and  $A \in \mathscr{S}$ , and knowing when this is the case is of considerable interest. As with all kernels, the potential kernel  $U_{\alpha}$  defines two operators, operating on the right on functions, and operating on the left on positive measures. If  $f: S \to \mathbb{R}$  is measurable then, giving the right potential operator in its many forms,

$$egin{aligned} U_lpha f(x) &= \int_S U_lpha(x,dy) f(y) = \int_0^\infty e^{-lpha t} P_t f(x) \, dt \ &= \int_0^\infty e^{-lpha t} \int_S P_t(x,dy) f(y) = \int_0^\infty e^{-lpha t} \mathbb{E}[f(X_t) \mid X_0 = x] \, dt, \quad x \in S. \end{aligned}$$

assuming that the various integrals make sense. This will be the case in particular if f is nonnegative, or if  $f \in \mathscr{B}$  and  $\alpha > 0$ .

If lpha>0 , then  $U_lpha(x,S)=rac{1}{lpha}$  for all  $x\in S.$ Proof For  $x\in S$  ,

$$U_{\alpha}(x,S) = \int_{0}^{\infty} e^{-\alpha t} P_{t}(x,S) dt = \int_{0}^{\infty} e^{-\alpha t} dt = \frac{1}{\alpha}$$
(16.2.27)

It follows that for  $\alpha \in (0, \infty)$ , the right potential operator  $U_{\alpha}$  is a bounded, linear operator on  $\mathscr{B}$  with  $||U_{\alpha}|| = \frac{1}{\alpha}$ . It also follows that  $\alpha U_{\alpha}$  is a probability kernel. This kernel has a nice interpretation.

If  $\alpha > 0$  then  $\alpha U_{\alpha}(x, \cdot)$  is the conditional distribution of  $X_{\tau}$  where  $\tau$  is independent of X and has the exponential distribution on  $[0, \infty)$  with parameter  $\alpha$ .

Proof

Suppose that  $x \in S$  and  $A \in S$ . The random time  $\tau$  has PDF  $f(t) = \alpha e^{-\alpha t}$  for  $t \in [0, \infty)$ . Hence, conditioning on  $\tau$  gives

$$\mathbb{P}(X_{\tau} \in A \mid X_0 = x) = \int_0^{\infty} \alpha e^{-\alpha t} \mathbb{P}(X_{\tau} \in A \mid \tau = t, X_0 = x) dt$$
(16.2.28)

But by the substitution rule and the assumption of independence,

$$\mathbb{P}(X_{\tau} \in A \mid \tau = t, X_0 = x) = \mathbb{P}(X_t \in A \mid \tau = t, X_0 = x) = \mathbb{P}(X_t \in A \mid X_0 = x) = P_t(x, A)$$
(16.2.29)

Substituting gives

$$\mathbb{P}(X_{\tau} \in A \mid X_0 = x) = \int_0^\infty \alpha e^{-\alpha t} P_t(x, A) \, dt = \alpha U_{\alpha}(x, A) \tag{16.2.30}$$

So  $\alpha U_{\alpha}$  is a transition probability kernel, just as  $P_t$  is a transition probability kernel, but corresponding to the *random* time  $\tau$  (with  $\alpha \in (0, \infty)$  as a parameter), rather than the deterministic time  $t \in [0, \infty)$ . As in the discrete case, the potential kernel can also be interpreted in economic terms. Suppose that  $A \in \mathscr{S}$  and that we receive money at a rate of one unit per unit time whenever the process X is in A. Then U(x, A) is the expected total amount of money that we receive, starting in state  $x \in S$ . But again, money that we receive later is of less value to us *now* than money that we will receive sooner. Specifically, suppose that one monetary unit at time  $t \in [0, \infty)$  has a present value of  $e^{-\alpha t}$  where  $\alpha \in (0, \infty)$  is the *inflation factor* or *discount factor*. The  $U_{\alpha}(x, A)$  is the total, expected, discounted amount that we receive, starting in  $x \in S$ . A bit more generally, suppose that  $f \in \mathscr{B}$  and that f(x) is the reward (or cost, depending on the sign) per unit time that we receive when the process is in state  $x \in S$ . Then  $U_{\alpha}f(x)$  is the expected, total, discounted reward, starting in state  $x \in S$ .

For the left potential operator, if  $\mu$  is a positive measure on  $\mathscr{S}$  then

$$egin{aligned} \mu U_lpha(A) &= \int_S \mu(dx) U_lpha(x,A) = \int_0^\infty e^{-lpha t} \mu P_t(A) \, dt \ &= \int_0^\infty e^{-lpha t} \left[ \int_S \mu(dx) P_t(x,A) 
ight] dt = \int_0^\infty e^{-lpha t} \left[ \int_S \mu(dx) \mathbb{P}(X_t \in A) 
ight] dt, \quad A \in \mathscr{S} \end{aligned}$$

In particular, suppose that  $\alpha > 0$  and that  $\mu$  is a probability measure and  $X_0$  has distribution $\mu$ . Then  $\mu P_t$  is the distribution of  $X_t$  for  $t \in [0, \infty)$ , and hence from the last result,  $\alpha \mu U_{\alpha}$  is the distribution of  $X_{\tau}$ , where again,  $\tau$  is independent of X and has the exponential distribution on  $[0, \infty)$  with parameter  $\alpha$ . The family of potential kernels gives the same information as the family of transition kernels.

The resolvent  $U = \{U_{\alpha} : \alpha \in (0, \infty)\}$  completely determines the family of transition kernels  $P = \{P_t : t \in (0, \infty)\}$ . Proof

Proof

Note that for  $x \in S$  and  $A \in S$ , the function  $\alpha \mapsto U_{\alpha}(x, A)$  on  $(0, \infty)$  is the Laplace transform of the function  $t \mapsto P_t(x, A)$  on  $[0, \infty)$ . The Laplace transform of a function determines the function completely.

It follows that the resolvent  $\{U_{\alpha} : \alpha \in [0, \infty)\}$ , along with the initial distribution, completely determine the finite dimensional distributions of the Markov process **X**. This is much more important here in the continuous-time case than in the discrete-time case, since the transition kernels  $P_t$  cannot be generated from a single transition kernel. The potential kernels commute with each other and with the transition kernels.

Suppose that  $\alpha, \beta, t \in [0, \infty)$ . Then (as kernels),

1. 
$$P_t U_{\alpha} = U_{\alpha} P_t = \int_0^{\infty} e^{-\alpha s} P_{s+t} ds$$
  
2.  $U_{\alpha} U_{\beta} = \int_0^{\infty} \int_0^{\infty} e^{-\alpha s} e^{-\beta t} P_{s+t} ds ds$ 

Proof

Suppose that  $f \in \mathscr{B}$  is nonnegative. The interchanges of operators and integrals below are interchanges of integrals, and are justified since the integrands are nonnegative. The other tool used is the semigroup property of  $\mathbf{P} = \{P_t : t \in [0, \infty)\}$ .

1. Directly,

$$U_{\alpha}P_{t}f = \int_{0}^{\infty} e^{-\alpha s} P_{s}P_{t}f \, ds = \int_{0}^{\infty} e^{-\alpha s} P_{s+t}f \, ds \tag{16.2.31}$$

The other direction involves an interchange.

$$P_t U_{\alpha} f = P_t \int_0^\infty e^{-\alpha s} P_s f \, ds = \int_0^\infty e^{-\alpha s} P_t P_s f \, ds = \int_0^\infty e^{-\alpha s} P_{s+t} f \, ds \tag{16.2.32}$$

2. First

$$\begin{aligned} U_{\alpha}U_{\beta}f &= \int_{0}^{\infty} e^{-\alpha s} P_{s}U_{\beta}f \, ds = \int_{0}^{\infty} e^{-\alpha s} P_{s} \int_{0}^{\infty} e^{-\beta t} P_{t}f \, dt \\ &= \int_{0}^{\infty} e^{-\alpha s} \int_{0}^{\infty} e^{-\beta t} P_{s}P_{t}f \, ds \, dt = \int_{0}^{\infty} \int_{0}^{\infty} e^{-\alpha s} e^{-\beta t} P_{s+t}f \, ds \, dt \end{aligned}$$

The other direction is similar.

The same identities hold for the right operators on the entire space  $\mathscr{B}$  under the additional restriction that  $\alpha > 0$  and  $\beta > 0$ . The fundamental equation that relates the potential kernels, known as the *resolvent equation*, is given in the next theorem:

If  $lpha,\ eta\in[0,\infty)$  with  $lpha\leeta$  then (as kernels)  $U_lpha=U_eta+(eta-lpha)U_lpha U_eta$  .

Proof

If  $\alpha = \beta$  the equation is trivial, so assume  $\alpha < \beta$ . Suppose that  $f \in \mathscr{B}$  is nonnegative. From the previous result,

$$U_{\alpha}U_{\beta}f = \int_{0}^{\infty} \int_{0}^{\infty} e^{-\alpha s} e^{-\beta t} P_{s+t} f \, dt \, ds \tag{16.2.33}$$

The transformation u = s + t, v = s maps  $[0, \infty)^2$  one-to-one onto  $\{(u, v) \in [0, \infty)^2 : u \ge v\}$ . The inverse transformation is s = v, t = u - v with Jacobian -1. Hence we have

$$\begin{split} U_{\alpha}U_{\beta}f &= \int_{0}^{\infty}\int_{0}^{u}e^{-\alpha v}e^{-\beta(u-v)}P_{u}f\,dv\,du = \int_{0}^{\infty}\left(\int_{0}^{u}e^{(\beta-\alpha)v}dv\right)e^{-\beta u}P_{u}f\,du \\ &= \frac{1}{\beta-\alpha}\int_{0}^{\infty}\left[e^{(\beta-\alpha)u}-1\right]e^{-\beta u}P_{u}f\,du \\ &= \frac{1}{\beta-\alpha}\left(\int_{0}^{\infty}e^{-\alpha u}P_{u}f\,du - \int_{0}^{\infty}e^{-\beta u}P_{u}f\,du\right) = \frac{1}{\beta-\alpha}(U_{\alpha}f-U_{\beta}f) \end{split}$$

Simplifying gives the result. Note that  $U_{\beta}f$  is finite since  $\beta > 0$ .

The same identity holds for the right potential operators on the entire space  $\mathscr{B}$ , under the additional restriction that  $\alpha > 0$ . For  $\alpha \in (0, \infty)$ ,  $U_{\alpha}$  is also an operator on the space  $\mathscr{C}_{0}$ .

If 
$$\alpha \in (0,\infty)$$
 and  $f \in \mathscr{C}_0$  then  $U_{\alpha}f \in \mathscr{C}_0$ .

Proof

Suppose that  $f \in \mathscr{C}_0$  and that  $(x_1, x_2, \ldots)$  is a sequence in S. Then  $P_t f \in \mathscr{C}_0$  for  $t \in [0, \infty)$ . Hence if  $x_n \to x \in S$  as  $n \to \infty$  then  $e^{-\alpha t} P_t f(x_n) \to e^{-\alpha t} P_t f(x)$  as  $n \to \infty$  for each  $t \in [0, \infty)$ . By the dominated convergence theorem,

$$U_{\alpha}f(x_n) = \int_0^\infty e^{-\alpha t} P_t f(x_n) \, dt \to \int_0^\infty e^{-\alpha t} P_t f(x) \, dt = U_{\alpha}f(x) \text{ as } n \to \infty \tag{16.2.34}$$

Hence  $U_{\alpha}f$  is continuous. Next suppose that  $x_n \to \infty$  as  $n \to \infty$ . This means that for every compact  $C \subseteq S$ , there exist  $m \in \mathbb{N}_+$  such that  $x_n \notin C$  for n > m. Then  $e^{-\alpha t}P_t f(x_n) \to 0$  as  $n \to \infty$  for each  $t \in [0, \infty)$ . Again by the dominated convergence theorem,

$$U_{\alpha}f(x_n) = \int_0^\infty e^{-\alpha t} P_t f(x_n) \, dt \to 0 \text{ as } n \to \infty \tag{16.2.35}$$

So  $U_lpha f\in \mathscr{C}_0$  .

# If $f\in \mathscr{C}_0$ then $lpha U_lpha f o f$ as $lpha o\infty.$

Proof

Convergence is with respect to the supremum norm on  $\mathscr{C}_0$ , of course. Suppose that  $f \in \mathscr{C}_0$ . Note first that with a change of variables  $s = \alpha t$ ,

l

$$\alpha U_{\alpha}f = \int_0^{\infty} \alpha e^{-\alpha t} P_t f \, dt = \int_0^{\infty} e^{-s} P_{s/\alpha}f \, ds \tag{16.2.36}$$

and hence

$$|\alpha U_{\alpha}f - f| = \left| \int_{0}^{\infty} e^{-s} \left( P_{s/\alpha}f - f \right) ds \right| \le \int_{0}^{\infty} e^{-s} \left| P_{s/\alpha}f - f \right| \, ds \le \int_{0}^{\infty} e^{-s} \left\| P_{s/\alpha}f - f \right\| \, ds \tag{16.2.37}$$

So it follows that

$$\|lpha U_{lpha} f - f\| \le \int_{0}^{\infty} e^{-s} \|P_{s/lpha} f - f\| ds$$
 (16.2.38)

But  $\|P_{s/\alpha}f - f\| \to 0$  as  $\alpha \to \infty$  and hence by the dominated convergence theorem,  $\int_0^\infty e^{-s} \|P_{s/\alpha}f - f\| \, ds \to 0$  as  $\alpha \to \infty$ .

# Infinitesimal Generator

In continuous time, it's not at all clear how we could construct a Markov process with desired properties, say to model a real system of some sort. Stated mathematically, the existential problem is how to construct the family of transition kernels  $\{P_t : t \in [0, \infty)\}$  so that the semigroup property  $P_s P_t = P_{s+t}$  is satisfied for all  $s, t \in [0, \infty)$ . The answer, as for similar problems in the deterministic world, comes essentially from calculus, from a type of derivative.

The *infinitesimal generator* of the Markov process X is the operator  $G : \mathscr{D} \to \mathscr{C}_0$  defined by

$$Gf = \lim_{t \downarrow 0} \frac{P_t f - f}{t} \tag{16.2.39}$$

on the domain  $\mathscr{D} \subseteq \mathscr{C}_0$  for which the limit exists.

As usual, the limit is with respect to the supremum norm on  $\mathscr{C}_0$ , so  $f \in \mathscr{D}$  and Gf = g means that  $f, g \in \mathscr{C}_0$  and

$$\left\|\frac{P_t f - f}{t} - g\right\| = \sup\left\{\left|\frac{P_t f(x) - f(x)}{t} - g(x)\right| : x \in S\right\} \to 0 \text{ as } t \downarrow 0$$

$$(16.2.40)$$

So in particular,

$$Gf(x) = \lim_{t \downarrow 0} rac{P_t f(x) - f(x)}{t} = \lim_{t \downarrow 0} rac{\mathbb{E}[f(X_t) \mid X_0 = x] - f(x)}{t}, \quad x \in S$$
 (16.2.41)

The domain  $\mathscr{D}$  is a subspace of  $\mathscr{C}_0$  and the generator G is a linear operator on  $\mathscr{D}$ 

 $\begin{array}{l} \text{1. If } f\in \mathscr{D} \text{ and } c\in \mathbb{R} \text{ then } cf\in \mathscr{D} \text{ and } G(cf)=cGf.\\ \text{2. If } f, \ g\in \mathscr{D} \text{ then } f+g\in \mathscr{D} \text{ and } G(f+g)=Gf+Gg \ . \end{array}$ 

Proof

These are simple results that depend on the linearity of  $P_t$  for  $t \in [0, \infty)$  and basic results on convergence.

1. If  $f \in \mathscr{D}$  then

$$\frac{P_t(cf) - (cf)}{t} = c \frac{P_t f - f}{t} \to cGf \text{ as } t \downarrow 0$$
(16.2.42)

2. If  $f, \, g \in \mathscr{D}$  then

$$\frac{P_t(f+g) - (f+g)}{t} = \frac{P_t f - f}{t} + \frac{P_t g - g}{t} \rightarrow Gf + Gg \text{ as } t \downarrow 0$$

$$(16.2.43)$$

Note *G* is the (right) derivative at 0 of the function  $t \mapsto P_t f$ . Because of the semigroup property, this differentiability property at 0 implies differentiability at arbitrary  $t \in [0, \infty)$ . Moreover, the infinitesimal operator and the transition operators commute:

If  $f \in \mathscr{D}$  and  $t \in [0, \infty)$ , then  $P_t f \in \mathscr{D}$  and the following derivative rules hold with respect to the supremum norm.

- 1.  $P'_t f = P_t G f$ , the Kolmogorov forward equation
- 2.  $P'_t f = GP_t f$ , the Kolmogorov backward equation

Proof

Let  $f \in \mathscr{D}$ . All limits and statements about derivatives and continuity are with respect to the supremum norm.

1. By assumption,

$$\frac{1}{h}(P_hf - f) \to Gf \text{ as } h \downarrow 0 \tag{16.2.44}$$

Since  $P_t$  is a bounded, linear operator on the space  $\mathscr{C}_0$ , it preserves limits, so

$$\frac{1}{h}(P_t P_h f - P_t f) = \frac{1}{h}(P_{t+h} f - P_t f) \to P_t G f \text{ as } h \downarrow 0$$
(16.2.45)

This proves the result for the derivative from the right. But since  $t \mapsto P_t f$  is continuous, the the result is also true for the two-sided derivative. 2. From part (a), we now know that

$$\frac{1}{h}(P_h P_t f - P_t f) = \frac{1}{h}(P_{t+h} f - P_t f) \to P_t G f \text{ as } h \to 0$$
(16.2.46)

By definition, this means that  $P_t f \in \mathscr{D}$  and  $GP_t f = P_t G f = P_t' f$  .

The last result gives a possible solution to the dilema that motivated this discussion in the first place. If we want to construct a Markov process with desired properties, to model a a real system for example, we can start by constructing an appropriate generator G and then solve the initial value problem

$$P'_t = GP_t, \quad P_0 = I \tag{16.2.47}$$

to obtain the transition operators  $P = \{P_t : t \in [0, \infty)\}$ . The next theorem gives the relationship between the potential operators and the infinitesimal operator, which in some ways is better. This relationship is analogous to the relationship between the potential operators and the one-step operator given above in discrete time

Suppose  $\alpha \in (0,\infty)$ .

 $\begin{array}{l} \text{1. If } f\in \mathscr{D} \text{ the } Gf\in \mathscr{C}_0 \text{ and } f+U_\alpha Gf=\alpha U_\alpha f \\ \text{2. If } f\in \mathscr{C}_0 \text{ then } U_\alpha f\in \mathscr{D} \text{ and } f+GU_\alpha f=\alpha U_\alpha f \,. \end{array}$ 

Proof

1. By definition, if  $f \in \mathscr{D}$  then  $Gf \in \mathscr{C}_0$ . Hence using the previous result,

$$f + U_{\alpha}Gf = f + \int_{0}^{\infty} e^{-\alpha t} GP_{t}f \, dt = f + \int_{0}^{\infty} e^{-\alpha t} P_{t}'f \, dt$$
(16.2.48)

Integrating by parts (with  $u = e^{-\alpha t}$  and  $dv = P_t'f \, dt$ ) gives

$$f + GU_{\alpha}f = f - e^{-\alpha t}P_t f \Big|_0^{\infty} + \alpha \int_0^{\infty} e^{-\alpha t}P_t f dt$$
(16.2.49)

But  $e^{-\alpha t}P_t f \to 0$  as  $t \to \infty$  while  $P_0 f = f$ . The last term is  $\alpha U_{\alpha} f$ .

2. Suppose that  $f\in \mathscr{C}_0.$  From the result above and the substitution u=s+t ,

$$P_t U_{\alpha} f = \int_0^\infty e^{-\alpha s} P_{s+t} f \, ds = \int_t^\infty e^{-\alpha(u-t)} P_u f \, du = e^{\alpha t} \int_t^\infty e^{-\alpha u} P_u f \, du \tag{16.2.50}$$

Hence

$$\frac{P_t U_\alpha f - U_\alpha f}{t} = \frac{1}{t} \left[ e^{\alpha t} \int_t^\infty e^{-\alpha u} P_u f \, du - U_\alpha f \right]$$
(16.2.51)

Adding and subtracting  $e^{\alpha u}U_{\alpha}f$  and combining integrals gives

$$\begin{aligned} \frac{P_t U_{\alpha} f - U_{\alpha} f}{t} &= \frac{1}{t} \bigg[ e^{\alpha t} \int_t^{\infty} e^{-\alpha u} P_u f \, du - e^{\alpha t} \int_0^{\infty} e^{-\alpha u} P_u f \, du \bigg] + \frac{e^{\alpha t} - 1}{t} U_{\alpha} f \\ &= -e^{\alpha t} \frac{1}{t} \int_0^t e^{-\alpha s} P_s f \, ds + \frac{e^{\alpha t} - 1}{t} U_{\alpha} f \end{aligned}$$

Since  $s \mapsto P_s f$  is continuous, the first term converges to -f as  $t \downarrow 0$ . The second term converges to  $\alpha U_{\alpha} f$  as  $t \downarrow 0$ .

For  $\alpha > 0$ , the operators  $U_{\alpha}$  and *G* have an inverse relationship.

Suppose again that 
$$\alpha \in (0, \infty)$$
.  
1.  $U_{\alpha} = (\alpha I - G)^{-1} : \mathscr{C}_{0} \to \mathscr{D}$   
2.  $G = \alpha I - U_{\alpha}^{-1} : \mathscr{D} \to \mathscr{C}_{0}$   
Proof  
Recall that  $U_{\alpha} : \mathscr{C}_{0} \to \mathscr{D}$  and  $G : \mathscr{D} \to \mathscr{C}_{0}$   
1. By part(a) the previous result we have  $\alpha U_{\alpha} - U_{\alpha}G = I$  so  $U_{\alpha}(\alpha I - G) = I$ . By part (b) we have  $\alpha U_{\alpha} - GU_{\alpha} = I$  so  $(\alpha I - G)U_{\alpha} = I$ .

2. This follows from (a).

So, from the generator *G* we can determine the potential operators  $U = \{U_{\alpha} : \alpha \in (0, \infty)\}$ , which in turn determine the transition operators  $P = \{P_t : t \in (0, \infty)\}$ . In continuous time, transition operators  $P = \{P_t : t \in [0, \infty)\}$  can be obtained from the single, infinitesimal operator *G* in a way that is reminiscent of the fact that in discrete time, the transition operators  $P = \{P^n : n \in \mathbb{N}\}$  can be obtained from the single, one-step operator *P*.

# Examples and Applications

Our first example is essentially deterministic.

Consider the Markov process  $X = \{X_t : t \in [0, \infty)\}$  on  $\mathbb{R}$  satisfying the ordinary differential equation

$$rac{d}{dt}X_t=g(X_t),\quad t\in[0,\infty)$$
(16.2.52)

where  $g: \mathbb{R} \to \mathbb{R}$  is Lipschitz continuous. The infinitesimal operator G is given by Gf(x) = f'(x)g(x) for  $x \in \mathbb{R}$  on the domain  $\mathscr{D}$  of functions  $f: \mathbb{R} \to \mathbb{R}$  where  $f \in \mathscr{C}_0$  and  $f' \in \mathscr{C}_0$ .

Proof

Recall that the only source of randomness in this process is the initial sate  $X_0$ . By the continuity assumptions on g, there exists a unique solution  $X_t(x)$  to the differential equation with initial value  $X_0 = x$ , defined for all  $t \in [0, \infty)$ . The transition operator  $P_t$  for  $t \in [0, \infty)$  is defined on  $\mathscr{B}$  by  $P_t f(x) = f[X_t(x)]$  for  $x \in \mathbb{R}$ . By the ordinary chain rule, if f is differentiable,

$$\frac{P_t f(x) - f(x)}{t} = \frac{f[X_t(x)] - f(x)}{t} \to f'(x)g(x) \text{ as } t \downarrow 0$$
(16.2.53)

Our next example considers the Poisson process as a Markov process. Compare this with the binomial process above.

Let  $N = \{N_t : t \in [0, \infty)\}$  denote the Poisson process on  $\mathbb{N}$  with rate  $\beta \in (0, \infty)$ . Define the Markov process  $X = \{X_t : t \in [0, \infty)\}$  by  $X_t = X_0 + N_t$  where  $X_0$  takes values in  $\mathbb{N}$  and is independent of N.

1. For  $t \in [0, \infty)$ , show that the probability transition matrix  $P_t$  of  $\boldsymbol{X}$  is given by

$$P_t(x,y) = e^{-eta t} rac{(eta t)^{y-x}}{(y-x)!}, \quad x,\,y \in \mathbb{N},\, y \geq x$$
 (16.2.54)

2. For  $\alpha \in [0, \infty)$ , show that the potential matrix  $U_{\alpha}$  of **X** is given by

$$U_{lpha}(x,y) = rac{1}{lpha + eta} \left(rac{eta}{lpha + eta}
ight)^{y-x}, \quad x, \, y \in \mathbb{N}, \, y \ge x$$
 (16.2.55)

3. For  $\alpha > 0$  and  $x \in \mathbb{N}$ , identify the probability distribution defined by  $\alpha U_{\alpha}(x, \cdot)$ . 4. Show that the infinitesimal matrix G of X is given by  $G(x, x) = -\beta$ ,  $G(x, x+1) = \beta$  for  $x \in \mathbb{N}$ . Solutions

1. Note that for  $t \in [0, \infty)$  and  $x \in \mathbb{N}$ ,  $P_t(x, \cdot)$  is the (discrete) PDF of  $x + N_t$  since  $N_t$  has the Poisson distribution with parameter  $\beta t$ . 2. Let  $\alpha \in [0, \infty)$  and let  $x, y \in \mathbb{N}$  with  $x \leq y$ . Then

$$egin{aligned} U_lpha(x,y) &= \int_0^\infty e^{-lpha t} P_t(x,y)\,dt = \int_0^\infty e^{-lpha t} e^{-eta t} rac{(eta t)^{y-x}}{(y-x)!}\,dt \ &= rac{eta^{y-x}}{(y-x)!}\int_0^\infty e^{-(lpha+eta)t}t^{y-x}\,dt \end{aligned}$$

The change of variables  $s = (\alpha + \beta)t$  gives

$$U_{\alpha}(x,y) = \frac{\beta^{y-x}}{(y-x)!(\alpha+\beta)^{y-x+1}} \int_0^\infty e^{-s} s^{y-x} \, ds \tag{16.2.56}$$

But the last integral is  $\Gamma(y-x+1)=(y-x)!$  . Simplifying gives the result. 3. For lpha>0 ,

$$\alpha U_{\alpha}(x,y) = \frac{\alpha}{\alpha + \beta} \left(\frac{\beta}{\alpha + \beta}\right)^{y-x}, \quad x, y \in \mathbb{N}, \ y \ge x$$
(16.2.57)

As a function of y for fixed x, this is the PDF of  $x + Y_{\alpha}$  where  $Y_{\alpha}$  has the geometric distribution with parameter  $\frac{\alpha}{\alpha+\beta}$ .

4. Note that for  $x, y \in \mathbb{N}$ ,  $G(x, y) = \frac{d}{dt}P_t(x, y) \mid_{t=0}$ . By simple calculus, this is  $-\beta$  if y = x,  $\beta$  if y = x+1, and 0 otherwise.

# 16.3: Introduction to Discrete-Time Chains

In this and the next several sections, we consider a Markov process with the discrete time space  $\mathbb{N}$  and with a discrete (countable) state space. Recall that a Markov process with a discrete state space is called a *Markov chain*, so we are studying *discrete-time Markov chains*.

# **Review**

We will review the basic definitions and concepts in the general introduction. With both time and space discrete, many of these definitions and concepts simplify considerably. As usual, our starting point is a probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ , so  $\Omega$  is the sample space,  $\mathscr{F}$  the  $\sigma$ -algebra of events, and  $\mathbb{P}$  the probability measure on  $(\Omega, \mathscr{F})$ . Let  $\mathbf{X} = (X_0, X_1, X_2, \ldots)$  be a stochastic process defined on the probability space, with time space  $\mathbb{N}$  and with countable state space S. In the context of the general introduction, S is given the power set  $\mathscr{P}(S)$  as the  $\sigma$ -algebra, so all subsets of S are measurable, as are all functions from S into another measurable space. Counting measure # is the natural measure on S, so integrals over S are simply sums. The same comments apply to the time space  $\mathbb{N}$ : all subsets of  $\mathbb{N}$  are measurable and counting measure # is the natural measure on  $\mathbb{N}$ .

The vector space  $\mathscr{B}$  consisting of bounded functions  $f : S \to \mathbb{R}$  will play an important role. The norm that we use is the *supremum norm* defined by

$$\|f\| = \sup\{|f(x)| : x \in S\}, \quad f \in \mathscr{B}$$

$$(16.3.1)$$

For  $n \in \mathbb{N}$ , let  $\mathscr{F}_n = \sigma\{X_0, X_1, \dots, X_n\}$ , the  $\sigma$ -algebra generated by the process up to time n. Thus  $\mathfrak{F} = \{\mathscr{F}_0, \mathscr{F}_1, \mathscr{F}_2, \dots\}$  is the natural filtration associated with X. We also let  $\mathscr{G}_n = \sigma\{X_n, X_{n+1}, \dots\}$ , the  $\sigma$ -algebra generated by the process from time n on. So if  $n \in \mathbb{N}$  represents the present time, then  $\mathscr{F}_n$  contains the events in the past and  $\mathscr{G}_n$  the events in the future.

# Definitions

We start with the basic definition of the Markov property: the past and future are conditionally independent, given the present.

 $\boldsymbol{X} = (X_0, X_1, X_2, \dots) \text{ is a Markov chain if } \mathbb{P}(A \cap B \mid X_n) = \mathbb{P}(A \mid X_n) \mathbb{P}(B \mid X_n) \quad \text{ for every } n \in \mathbb{N}, \, A \in \mathscr{F}_n \, \text{ and } B \in \mathscr{G}_n \, .$ 

There are a number of equivalent formulations of the Markov property for a discrete-time Markov chain. We give a few of these.

 $\boldsymbol{X} = (X_0, X_1, X_2, \ldots)$  is a Markov chain if either of the following equivalent conditions is satisfied:

1. 
$$\mathbb{P}(X_{n+1} = x \mid \mathscr{F}_n) = \mathbb{P}(X_{n+1} = x \mid X_n)$$
 for every  $n \in \mathbb{N}$  and  $x \in S$ .  
2.  $\mathbb{E}[f(X_{n+1}) \mid \mathscr{F}_n] = \mathbb{E}[f(X_{n+1}) \mid X_n]$  for every  $n \in \mathbb{N}$  and  $f \in \mathscr{B}$ .

Part (a) states that for  $n \in \mathbb{N}$ , the conditional probability density function of  $X_{n+1}$  given  $\mathscr{F}_n$  is the same as the conditional probability density function of  $X_{n+1}$  given  $X_n$ . Part (b) also states, in terms of expected value, that the conditional distribution of  $X_{n+1}$  given  $\mathscr{F}_n$  is the same as the conditional distribution of  $X_{n+1}$  given  $\mathscr{F}_n$ . Both parts are the Markov property looking just one time step in the future. But with discrete time, this is equivalent to the Markov property at general future times.

 $\boldsymbol{X} = (X_0, X_1, X_2, \ldots)$  is a Markov chain if either of the following equivalent conditions is satisfied:

1. 
$$\mathbb{P}(X_{n+k} = x \mid \mathscr{P}_n) = \mathbb{P}(X_{n+k} = x \mid X_n)$$
 for every  $n, k \in \mathbb{N}$  and  $x \in S$ .  
2.  $\mathbb{E}[f(X_{n+k}) \mid \mathscr{P}_n] = \mathbb{E}[f(X_{n+k}) \mid X_n]$  for every  $n, k \in \mathbb{N}$  and  $f \in \mathscr{B}$ .

Part (a) states that for  $n, k \in \mathbb{N}$ , the conditional probability density function of  $X_{n+k}$  given  $\mathscr{P}_n$  is the same as the conditional probability density function of  $X_{n+k}$  given  $X_n$ . Part (b) also states, in terms of expected value, that the conditional distribution of  $X_{n+k}$  given  $\mathscr{P}_n$  is the same as the conditional distribution of  $X_{n+k}$  given  $\mathscr{P}_n$ . In discrete time and space, the Markov property can also be stated without explicit reference to  $\sigma$ -algebras. If you are not familiar with measure theory, you can take this as the starting definition.

 $m{X}=(X_0,X_1,X_2,\ldots)$  is a Markov chain if for every  $n\in\mathbb{N}$  and every sequence of states  $(x_0,x_1,\ldots,x_{n-1},x,y)$ .

$$\mathbb{P}(X_{n+1} = y \mid X_0 = x_0, X_1 = x_1, \dots, X_{n-1} = x_{n-1}, X_n = x) = \mathbb{P}(X_{n+1} = y \mid X_n = x)$$
(16.3.2)

The theory of discrete-time Markov chains is simplified considerably if we add an additional assumption.

P

A Markov chain  $\boldsymbol{X} = (X_0, X_1, X_2, \ldots)$  is time homogeneous if

$$P(X_{n+k} = y \mid X_k = x) = \mathbb{P}(X_n = y \mid X_0 = x)$$
(16.3.3)

for every  $k, \ n \in \mathbb{N}$  and every  $x, \ y \in S.$ 

That is, the conditional distribution of  $X_{n+k}$  given  $X_k = x$  depends only on n. So if X is homogeneous (we usually don't bother with the *time* adjective), then the chain  $\{X_{k+n} : n \in \mathbb{N}\}$  given  $X_k = x$  is equivalent (in distribution) to the chain  $\{X_n : n \in \mathbb{N}\}$  given  $X_0 = x$ . For this reason, the initial distribution is often unspecified in the study of Markov chains—if the chain is in state  $x \in S$  at a particular time  $k \in \mathbb{N}$ , then it doesn't really matter how the chain got to state x; the process essentially "starts over", independently of the past. The term *stationary* is sometimes used instead of homogeneous.

From now on, we will usually assume that our Markov chains are homogeneous. This is not as big of a loss of generality as you might think. A non-homogeneous Markov chain can be turned into a homogeneous Markov process by enlarging the state space, as shown in the introduction to general Markov processes, but at the cost of creating an uncountable state space. For a homogeneous Markov chain, if k,  $n \in \mathbb{N}$ ,  $x \in S$ , and  $f \in \mathscr{B}$ , then

$$\mathbb{E}[f(X_{k+n}) \mid X_k = x] = \mathbb{E}[f(X_n) \mid X_0 = x]$$
(16.3.4)

# Stopping Times and the Strong Markov Property

Consider again a stochastic process  $\mathbf{X} = (X_0, X_1, X_2, ...)$  with countable state space S, and with the natural filtration  $\mathfrak{F} = (\mathscr{F}_0, \mathscr{F}_1, \mathscr{F}_2, ...)$  as given above. Recall that a random variable  $\tau$  taking values in  $\mathbb{N} \cup \{\infty\}$  is a *stopping time* or a *Markov time* for  $\mathbf{X}$  if  $\{\tau = n\} \in \mathscr{F}_n$  for each  $n \in \mathbb{N}$ . Intuitively, we can tell whether or not  $\tau = n$  by observing the chain up to time n. In a sense, a stopping time is a random time that does not require that we see into the future. The following result gives the quintessential examples of stopping times.

Suppose again  $X = \{X_n : n \in \mathbb{N}\}$  is a discrete-time Markov chain with state space *S* as defined above. For  $A \subseteq S$ , the following random times are stopping times:

1.  $\rho_A = \inf\{n \in \mathbb{N} : X_n \in A\}$ , the entrance time to A. 2.  $\tau_A = \inf\{n \in \mathbb{N}_+ : X_n \in A\}$ , the hitting time to A. Proof For  $n \in \mathbb{N}$ 1.  $\{\rho_A = n\} = \{X_0 \notin A, X_1 \notin A, \dots, X_{n-1} \notin A, X_n \in A\} \in \mathscr{F}_n$ 2.  $\{\tau_A = n\} = \{X_1 \notin A, X_2 \notin A, \dots, X_{n-1} \notin A, X_n \in A\} \in \mathscr{F}_n$ 

An example of a random time that is generally *not* a stopping time is the *last* time that the process is in *A*:

$$\zeta_A = \max\{n \in \mathbb{N}_+ : X_n \in A\}$$

$$(16.3.5)$$

We cannot tell if  $\zeta_A = n$  without looking into the future:  $\{\zeta_A = n\} = \{X_n \in A, X_{n+1} \notin A, X_{n+2} \notin A, \ldots\}$  for  $n \in \mathbb{N}$ .

If  $\tau$  is a stopping time for  $\boldsymbol{X}$ , the  $\sigma$ -algebra associated with  $\tau$  is

$$\mathscr{F}_{ au} = \{A \in \mathscr{F} : A \cap \{ au = n\} \in \mathscr{F}_n ext{ for all } n \in \mathbb{N}\}$$

$$(16.3.6)$$

Intuitively,  $\mathscr{F}_{\tau}$  contains the events that can be described by the process up to the random time  $\tau$ , in the same way that  $\mathscr{F}_n$  contains the events that can be described by the process up to the deterministic time  $n \in \mathbb{N}$ . For more information see the section on filtrations and stopping times.

The *strong Markov property* states that the future is independent of the past, given the present, when the present time is a stopping time. For a discrete-time Markov chain, the ordinary Markov property implies the strong Markov property.

If  $\mathbf{X} = (X_0, X_1, X_2, ...)$  is a discrete-time Markov chain then  $\mathbf{X}$  has the strong Markov property. That is, if  $\tau$  is a finite stopping time for  $\mathbf{X}$  then 1.  $\mathbb{P}(X_{\tau+k} = x \mid \mathscr{F}_{\tau}) = \mathbb{P}(X_{\tau+k} = x \mid X_{\tau})$  for every  $k \in \mathbb{N}$  and  $x \in S$ . 2.  $\mathbb{E}[f(X_{\tau+k}) \mid \mathscr{F}_{\tau}] = \mathbb{E}[f(X_{\tau+k}) \mid X_{\tau}]$  for every  $k \in \mathbb{N}$  and  $f \in \mathscr{B}$ .

Part (a) states that the conditional probability density function of  $X_{\tau+k}$  given  $\mathscr{F}_{\tau}$  is the same as the conditional probability density function of  $X_{\tau+k}$  given just  $X_{\tau}$ . Part (b) also states, in terms of expected value, that the conditional distribution of  $X_{\tau+k}$  given  $\mathscr{F}_{\tau}$  is the same as the conditional distribution of  $X_{\tau+k}$  given just  $X_{\tau}$ . Assuming homogeneity as usual, the Markov chain  $\{X_{\tau+n} : n \in \mathbb{N}\}$  given  $X_{\tau} = x$  is equivalent in distribution to the chain  $\{X_n : n \in \mathbb{N}\}$  given  $X_0 = x$ .

# **Transition Matrices**

Suppose again that  $X = (X_0, X_1, X_2, ...)$  is a homogeneous, discrete-time Markov chain with state space *S*. With a discrete state space, the transition kernels studied in the general introduction become transition *matrices*, with rows and columns indexed by *S* (and so perhaps of infinite size). The kernel operations become familiar matrix operations. The results in this section are special cases of the general results, but we sometimes give independent proofs for completeness, and because the proofs are simpler. You may want to review the section on kernels in the chapter on expected value.

For  $n \in \mathbb{N}$  let

$$P_n(x,y) = \mathbb{P}(X_n = y \mid X_0 = x), \quad (x,y) \in S \times S$$
(16.3.7)

The matrix  $P_n$  is the *n*-step *transition probability matrix* for **X**.

Thus,  $y \mapsto P_n(x, y)$  is the probability density function of  $X_n$  given  $X_0 = x$ . In particular,  $P_n$  is a *probability matrix* (or *stochastic matrix*) since  $P_n(x, y) \ge 0$  for  $(x, y) \in S^2$  and  $\sum_{y \in S} P(x, y) = 1$  for  $x \in S$ . As with any nonnegative matrix on S,  $P_n$  defines a kernel on S for  $n \in \mathbb{N}$ :

$$P_n(x,A) = \sum_{y \in A} P_n(x,y) = \mathbb{P}(X_n \in A \mid X_0 = x), \quad x \in S, \ A \subseteq S$$
 (16.3.8)

So  $A \mapsto P_n(x, A)$  is the probability distribution of  $X_n$  given  $X_0 = x$ . The next result is the *Chapman-Kolmogorov* equation, named for Sydney Chapman and Andrei Kolmogorov. It gives the basic relationship between the transition matrices.

If  $m, \, n \in \mathbb{N}$  then  $P_m P_n = P_{m+n}$ 

Proof

This follows from the Markov and time-homogeneous properties and a basic conditioning argument. If  $x, z \in S$  then

$$P_{m+n}(x,z) = \mathbb{P}(X_{m+n} = z \mid X_0 = x) = \sum_{y \in S} \mathbb{P}(X_{m+n} = z \mid X_0 = x, X_m = y) \mathbb{P}(X_m = y \mid X_0 = x)$$
(16.3.9)

But by the Markov property and time-homogeneous properties

$$\mathbb{P}(X_{m+n} = z \mid X_0 = x, X_m = y) = \mathbb{P}(X_n = z \mid X_0 = y) = P_n(y, z)$$
(16.3.10)

Of course also  $\mathbb{P}(X_m=y \mid X_0=x) = P_m(x,y)$  Hence we have

$$P_{m+n}(x,z) = \sum_{y \in S} P_m(x,y) P_n(y,z)$$
(16.3.11)

The right side, by definition, is  $P_m P_n(x, z)$ .

It follows immediately that the transition matrices are just the matrix powers of the one-step transition matrix. That is, letting  $P = P_1$  we have  $P_n = P^n$  for all  $n \in \mathbb{N}$ . Note that  $P^0 = I$ , the identity matrix on S given by I(x, y) = 1 if x = y and 0 otherwise. The right operator corresponding to  $P^n$  yields an expected value.

Suppose that  $n \in \mathbb{N}$  and that  $f : S \to \mathbb{R}$ . Then, assuming that the expected value exists,

$$P^n f(x) = \sum_{y \in S} P^n(x,y) f(y) = \mathbb{E}[f(X_n) \mid X_0 = x], \quad x \in S$$
 (16.3.12)

Proof

This follows easily from the definitions:

$$P^n f(x) = \sum_{y \in S} P^n(x, y) f(y) = \sum_{y \in S} \mathbb{P}(X_n = y \mid X_0 = x) f(y) = \mathbb{E}[f(X_n) \mid X_0 = x], \quad x \in S$$
 (16.3.13)

The existence of the expected value is only an issue if S is infinite. In particular, the result holds if f is nonnegative or if  $f \in \mathscr{B}$  (which in turn would always be the case if S is finite). In fact,  $P^n$  is a linear *contraction operator* on the space  $\mathscr{B}$  for  $n \in \mathbb{N}$ . That is, if  $f \in \mathscr{B}$  then  $P^n f \in \mathscr{B}$  and  $||P^n f|| \leq ||f||$ . The left operator corresponding to  $P^n$  is defined similarly. For  $f : S \to \mathbb{R}$ 

$$fP^n(y) = \sum_{x \in S} f(x)P^n(x,y), \quad y \in S$$
 (16.3.14)

assuming again that the sum makes sense (as before, only an issue when S is infinite). The left operator is often restricted to nonnegative functions, and we often think of such a function as the density function (with respect to #) of a positive measure on S. In this sense, the left operator maps a density function to another density function.

A function  $f: S \to \mathbb{R}$  is *invariant* for *P* (or for the chain **X**) if fP = f.

Clearly if *f* is invariant, so that fP = f then  $fP^n = f$  for all  $n \in \mathbb{N}$ . If *f* is a probability density function, then so is *fP*.

If  $X_0$  has probability density function f, then  $X_n$  has probability density function  $fP^n$  for  $n \in \mathbb{N}$ .

Proof

Again, this follows easily from the definitions and a conditioning argument.

TF

$$\mathbb{P}(X_n = y) = \sum_{x \in S} \mathbb{P}(X_0 = x) \mathbb{P}(X_n = y \mid X_0 = x) = \sum_{x \in S} f(x) P^n(x, y) = f P^n(y), \quad y \in S$$
 (16.3.15)

In particular, if  $X_0$  has probability density function f, and f is invariant for X, then  $X_n$  has probability density function f for all  $n \in \mathbb{N}$ , so the sequence of variables  $X = (X_0, X_1, X_2, ...)$  is identically distributed. Combining two results above, suppose that  $X_0$  has probability density function f and that  $g: S \to \mathbb{R}$ . Assuming the expected value exists,  $\mathbb{E}[g(X_n)] = fP^ng$ . Explicitly,

$$\mathbb{E}[g(X_n)] = \sum_{x \in S} \sum_{y \in S} f(x) P^n(x, y) g(y)$$
(16.3.16)

It also follows from the last theorem that the distribution of  $X_0$  (the *initial distribution*) and the one-step transition matrix determine the distribution of  $X_n$  for each  $n \in \mathbb{N}$ . Actually, these basic quantities determine the *finite dimensional distributions* of the process, a stronger result.

Suppose that  $X_0$  has probability density function  $f_0$ . For any sequence of states  $(x_0, x_1, \ldots, x_n) \in S^n$ ,

$$\mathbb{P}(X_0 = x_0, X_1 = x_1, \dots, X_n = x_n) = f_0(x_0) P(x_0, x_1) P(x_1, x_2) \cdots P(x_{n-1}, x_n)$$
(16.3.17)

Proof

This follows directly from the Markov property and the multiplication rule of conditional probability:

$$\mathbb{P}(X_0 = x_0, X_1 = x_1, \dots, X_n = x_n) = \mathbb{P}(X_0 = x_0)\mathbb{P}(X_1 = x_1 \mid X_0 = x_0)\mathbb{P}(X_2 = x_2 \mid X_0 = x_0, X_1 = x_1)$$

$$\cdots \mathbb{P}(X_n = x_n \mid X_0 = x_0, \dots, X_{n-1} = x_{n-1})$$
(16.3.18)

But by the Markov property, this reduces to

$$\begin{split} \mathbb{P}(X_0 = x_0, X_1 = x_1, \dots, X_n = x_n) &= \mathbb{P}(X_0 = x_0) \mathbb{P}(X_1 = x_1 \mid X_0 = x_0) \mathbb{P}(X_2 = x_2 \mid X_1 = x_1) \cdots \mathbb{P}(X_n = x_n \mid X_{n-1} = x_{n-1}) \\ &= f_0(x_0) P(x_0, x_1) P(x_1, x_2) \cdots P(x_{n-1}, x_n) \end{split}$$

Computations of this sort are the reason for the term *chain* in the name *Markov chain*. From this result, it follows that given a probability matrix P on S and a probability density function f on S, we can construct a Markov chain  $\mathbf{X} = (X_0, X_1, X_2, ...)$  such that  $X_0$  has probability density function f and the chain has one-step transition matrix P. In applied problems, we often know the one-step transition matrix P from modeling considerations, and again, the initial distribution is often unspecified.

There is a natural graph (in the combinatorial sense) associated with a homogeneous, discrete-time Markov chain.

Suppose again that  $X = (X_0, X_1, X_2, ...)$  is a Markov chain with state space S and transition probability matrix P. The *state graph* of X is the directed graph with vertex set S and edge set  $E = \{(x, y) \in S^2 : P(x, y) > 0\}$ .

That is, there is a directed edge from x to y if and only if state x leads to state y in one step. Note that the graph may well have loops, since a state can certainly lead back to itself in one step. More generally, we have the following result:

Suppose again that  $X = (X_0, X_1, X_2, ...)$  is a Markov chain with state space S and transition probability matrix P. For  $x, y \in S$  and  $n \in \mathbb{N}_+$ , there is a directed path of length n in the state graph from x to y if and only if  $P^n(x, y) > 0$ .

Proof

This follows since  $P^n(x, y) > 0$  if and only if there exists a sequence of states  $(x_1, x_2, \ldots, x_{n-1})$  with  $P(x, x_1) > 0, P(x_1, x_2) > 0, \ldots, P(x_{n-1}, y) > 0$ . This is also precisely the condition for the existence of a directed path  $(x, x_1, \ldots, x_{n-1}, y)$  of length n from x to y in the state graph.

#### **Potential Matrices**

For  $\alpha \in (0, 1]$ , the  $\alpha$ -potential matrix  $R_{\alpha}$  of  $oldsymbol{X}$  is

$$R_lpha = \sum_{n=0}^\infty lpha^n P^n, \quad (x,y)\in S^2$$
 (16.3.19)

1.  $R = R_1$  is simply the *potential matrix* of **X**.

2. R(x, y) is the expected number of visits by **X** to  $y \in S$ , starting at  $x \in S$ .

Proof

First the definition of  $R_{\alpha}$  as an infinite series of matrices makes sense since  $P^n$  is a nonnegative matrix for each n. The interpretation of R(x, y) for  $(x, y) \in S^2$  comes from interchanging sum and expected value, again justified since the terms are nonnegative.

$$R(x,y) = \sum_{n=0}^{\infty} P^n(x,y) = \sum_{n=0}^{\infty} \mathbb{E}[\mathbf{1}(X_n = y) \mid X_0 = x] = \mathbb{E}\left(\sum_{n=0}^{\infty} \mathbf{1}(X_n = y) \mid X_0 = x\right) = \mathbb{E}[\#\{n \in \mathbb{N} : X_n = y\} \mid X_0 = x] \quad (16.3.20)$$

Note that it's quite possible that  $R(x, y) = \infty$  for some  $(x, y) \in S^2$ . In fact, knowing when this is the case is of considerable importance in recurrence and transience, which we study in the next section. As with any nonnegative matrix, the  $\alpha$ -potential matrix defines a kernel and defines left and right operators. For the kernel,

$$R_{lpha}(x,A) = \sum_{y \in A} R_{lpha}(x,y) = \sum_{n=0}^{\infty} lpha^n P^n(x,A), \quad x \in S, A \subseteq S$$
 (16.3.21)

In particular, R(x, A) is the expected number of visits by the chain to A starting in x:

$$R(x,A) = \sum_{y \in A} R(x,y) = \sum_{n=0}^{\infty} P^n(x,A) = \mathbb{E}\left[\sum_{n=0}^{\infty} \mathbf{1}(X_n \in A)\right], \quad x \in S, A \subseteq S$$
(16.3.22)

If  $lpha\in(0,1)$ , then  $R_lpha(x,S)=rac{1}{1-lpha}$  for all  $x\in S.$ 

Proof

Using geometric series,

$$R_{\alpha}(x,S) = \sum_{n=0}^{\infty} \alpha^{n} P^{n}(x,S) = \sum_{n=0}^{\infty} \alpha^{n} = \frac{1}{1-\alpha}$$
(16.3.23)

Hence  $R_{\alpha}$  is a bounded matrix for  $\alpha \in (0, 1)$  and  $(1 - \alpha)R_{\alpha}$  is a probability matrix. There is a simple interpretation of this matrix.

If  $\alpha \in (0, 1)$  then  $(1 - \alpha)R_{\alpha}(x, y) = \mathbb{P}(X_N = y \mid X_0 = x)$  for  $(x, y) \in S^2$ , where N is independent of X and has the geometric distribution on  $\mathbb{N}$  with parameter  $1 - \alpha$ .

### Proof

Let  $(x,y)\in S^2$  . Conditioning on N gives

$$\mathbb{P}(X_N = y \mid X_0 = x) = \sum_{n=0}^{\infty} \mathbb{P}(N = n) \mathbb{P}(X_N = y \mid X_0 = x, N = n)$$
(16.3.24)

But by the substitution rule and the assumption of independence,

$$\mathbb{P}(X_N = y \mid N = n, X_0 = x) = \mathbb{E}(X_n = y \mid N = n, X_0 = x) = \mathbb{P}(X_n = y \mid X_0 = x) = P^n(x, y)$$
(16.3.25)

Since *N* has the geometric distribution on *N* with parameter  $1 - \alpha$  we have  $\mathbb{P}(N = n) = (1 - \alpha)\alpha^n$ . Hence

$$\mathbb{P}(X_N = y \mid X_0 = x) = \sum_{n=0}^{\infty} (1 - \alpha) \alpha^n P^n(x, y) = (1 - \alpha) R_\alpha(x, y)$$
(16.3.26)

So  $(1-\alpha)R_{\alpha}$  can be thought of as a *transition matrix* just as  $P^n$  is a transition matrix, but corresponding to the *random time* N (with  $\alpha$  as a paraamter) rather than the *deterministic time* n. An interpretation of the potential matrix  $R_{\alpha}$  for  $\alpha \in (0, 1)$  can also be given in economic terms. Suppose that we receive one monetary unit each time the chain visits a fixed state  $y \in S$ . Then R(x, y) is the expected total reward, starting in state  $x \in S$ . However, typically money that we will receive at times distant in the future have less value to us *now* than money that we will receive soon. Specifically suppose that a monetary unit at time  $n \in \mathbb{N}$  has a *present value* of  $\alpha^n$ , so that  $\alpha$  is an *inflation factor* (sometimes also called a *discount factor*). Then  $R_{\alpha}(x, y)$  gives the expected total discounted reward, starting at  $x \in S$ .

The potential kernels  $\mathbf{R} = \{R_{\alpha} : \alpha \in (0, 1)\}$  completely determine the transition kernels  $\mathbf{P} = \{P_n : n \in \mathbb{N}\}$ .

Proof

Note that for  $(x, y) \in S^2$ , the function  $\alpha \mapsto R_{\alpha}(x, y)$  is a power series in  $\alpha$  with coefficients  $n \mapsto P^n(x, y)$ . In the language of combinatorics,  $\alpha \mapsto R_{\alpha}(x, y)$  is the *ordinary generating function* of the sequence  $n \mapsto P^n(x, y)$ . As noted above, this power series has radius of convergence at least 1, so we can extend the domain to  $\alpha \in (-1, 1)$ . Thus, given the potential matrices, we can recover the transition matrices by taking derivatives and evaluating at 0:

$$P^{n}(x,y) = \frac{1}{n!} \left[ \frac{d^{n}}{d\alpha^{n}} R_{\alpha}(x,y) \right]_{\alpha=0}$$

$$(16.3.27)$$

Of course, it's really only necessary to determine P, the one step transition kernel, since the other transition kernels are powers of P. In any event, it follows that the matrices  $\mathbf{R} = \{R_{\alpha} : \alpha \in (0,1)\}$ , along with the initial distribution, completely determine the finite dimensional distributions of the Markov chain  $\mathbf{X}$ . The potential matrices commute with each other and with the transition matrices.

# If $lpha,\,eta\in(0,1]$ and $k\in\mathbb{N}$ , then

1. 
$$P^k R_{\alpha} = R_{\alpha} P^k = \sum_{n=0}^{\infty} \alpha^n P^{n+k}$$
  
2.  $R_{\alpha} R_{\beta} = R_{\beta} R_{\alpha} = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \alpha^m \beta^n P^{m+n}$ 

Proof

Distributing matrix products through matrix sums is allowed since the matrices are nonnegative.

1. Directly

$$R_{\alpha}P^{k} = \sum_{n=0}^{\infty} \alpha^{n}P^{n}P^{k} = \sum_{n=0}^{\infty} \alpha^{n}P^{n+k}$$
(16.3.28)

The other direction requires an interchange.

$$P^{k}R_{\alpha} = P^{k}\sum_{n=0}^{\infty} \alpha^{n}P^{n} = \sum_{n=0}^{\infty} \alpha^{n}P^{k}P^{n} = \sum_{n=0}^{\infty} \alpha^{n}P^{n+k}$$
(16.3.29)

2. First,

$$R_{\alpha}R_{\beta} = \sum_{m=0}^{\infty} \alpha^m P^m R_{\beta} = \sum_{m=0}^{\infty} \alpha^m P^m \left(\sum_{n=0}^{\infty} \beta^n P^n\right) = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \alpha^m \beta^n P^m P^n = \sum_{m=0}^{\infty} \sum_{n=0}^{\infty} \alpha^m \beta^n P^{m+n}$$
(16.3.30)

The other direction is similar.

The fundamental equation that relates the potential matrices is given next.

If  $lpha,\,eta\in(0,1]$  with  $lpha\geqeta$  then

$$\alpha R_{\alpha} = \beta R_{\beta} + (\alpha - \beta) R_{\alpha} R_{\beta} \tag{16.3.31}$$

Proof

If  $\alpha = \beta$  the equation is trivial, so assume  $\alpha > \beta$ . From the previous result,

$$R_{\alpha}R_{\beta} = \sum_{j=0}^{\infty} \sum_{k=0}^{\infty} \alpha^{j} q^{k} P^{j+k}$$

$$(16.3.32)$$

Changing variables to sum over n = j + k and k gives

$$R_{\alpha}R_{\beta} = \sum_{n=0}^{\infty} \sum_{k=0}^{n} \alpha^{n-k} \beta^{k} P^{n} = \sum_{n=0}^{\infty} \sum_{k=0}^{n} \left(\frac{\beta}{\alpha}\right)^{k} \alpha^{n} P^{n} = \sum_{n=0}^{\infty} \frac{1 - \left(\frac{\beta}{\alpha}\right)^{n+1}}{1 - \frac{\beta}{\alpha}} \alpha^{n} P^{n}$$
(16.3.33)

Simplifying gives

$$R_{\alpha}R_{\beta} = \frac{1}{\alpha - \beta} [\alpha R_{\alpha} - \beta R_{\beta}]$$
(16.3.34)

Note that since  $\beta < 1$ , the matrix  $R_{\beta}$  has finite values, so we don't have to worry about the dreaded indeterminate form  $\infty - \infty$ .

If  $lpha\in(0,1]$  then  $I+lpha R_lpha P=I+lpha PR_lpha=R_lpha$  .

Proof

From the result above,

$$I + \alpha R_{\alpha}P = I + \alpha PR_{\alpha} = I + \sum_{n=0}^{\infty} \alpha^{n+1}P^{n+1} = \sum_{n=0}^{\infty} \alpha^n P^n = R_{\alpha}$$
(16.3.35)

This leads to an important result: when  $\alpha \in (0, 1)$ , there is an inverse relationship between P and  $R_{\alpha}$ .

If  $\alpha \in (0, 1)$ , then 1.  $R_{\alpha} = (I - \alpha P)^{-1}$ 2.  $P = \frac{1}{\alpha} (I - R_{\alpha}^{-1})$ Proof

The matrices have finite values, so we can subtract. The identity  $I + \alpha R_{\alpha}P = R_{\alpha}$  leads to  $R_{\alpha}(I - \alpha P) = I$  and the identity  $I + \alpha PR_{\alpha} = R_{\alpha}$  leads to  $(I - \alpha P)R_{\alpha} = I$ . Hence (a) holds. Part (b) follows from (a).

This result shows again that the potential matrix  $R_{\alpha}$  determines the transition operator P.

#### Sampling in Time

If we sample a Markov chain at multiples of a fixed time k, we get another (homogeneous) chain.

Suppose that  $X = (X_0, X_1, X_2, ...)$  is an Markov chain with state space S and transition probability matrix P. For fixed  $k \in \mathbb{N}_+$ , the sequence  $X_k = (X_0, X_k, X_{2k}, ...)$  is a Markov chain on S with transition probability matrix  $P^k$ .

If we sample a Markov chain at a general increasing sequence of time points  $0 < n_1 < n_2 < \cdots$  in  $\mathbb{N}$ , then the resulting stochastic process  $Y = (Y_0, Y_1, Y_2, \ldots)$ , where  $Y_k = X_{n_k}$  for  $k \in \mathbb{N}$ , is still a Markov chain, but is not time homogeneous in general.

Recall that if *A* is a nonempty subset of *S*, then  $P_A$  is the matrix *P* restricted to  $A \times A$ . So  $P_A$  is a *sub*-stochastic matrix, since the row sums may be less than 1. Recall also that  $P_A^n$  means  $(P_A)^n$ , not  $(P^n)_A$ ; in general these matrices are different.

If *A* is a nonempty subset of *S* then for  $n \in \mathbb{N}$ ,

 $P_{A}^{n}(x,y) = \mathbb{P}(X_{1} \in A, X_{2} \in A, \dots, X_{n-1} \in A, X_{n} = y \mid X_{0} = x), \quad (x,y) \in A \times A$ (16.3.36)

That is,  $P_A^n(x, y)$  is the probability of going from state x to y in n steps, remaining in A all the while. In terms of the state graph of X, it is the sum of products of probabilities along paths of length n from x to y that stay inside A.

# **Examples and Applications**

Computational Exercises

Let  $\boldsymbol{X} = (X_0, X_1, \ldots)$  be the Markov chain on  $S = \{a, b, c\}$  with transition matrix

$\left\lceil \frac{1}{2} \right\rceil$	$\frac{1}{2}$	0 ]	
$P = \left  \frac{1}{4} \right $	0	$\frac{3}{4}$	(16.3.37)
L 1	0	0	

For the Markov chain X,

1. Draw the state graph. 2. Find  $\mathbb{P}(X_1 = a, X_2 = b, X_3 = c \mid X_0 = a)$ 

# 3. Find $P^2$

4. Suppose that  $g: S \to \mathbb{R}$  is given by g(a) = 1, g(b) = 2, g(c) = 3. Find  $\mathbb{E}[g(X_2) \mid X_0 = x]$  for  $x \in S$ .

5. Suppose that  $X_0$  has the uniform distribution on S. Find the probability density function of  $X_2$ .

Answer

- 1. The edge set is  $E=\{(a,a),(a,b),(b,a),(b,c),(c,a)\}$
- 2.  $P(a,a)P(a,b)P(b,c)=rac{3}{16}$

3. By standard matrix multiplication,

$$P^{2} = \begin{bmatrix} \frac{3}{8} & \frac{1}{4} & \frac{3}{8} \\ \frac{7}{8} & \frac{1}{8} & 0 \\ \frac{1}{2} & \frac{1}{2} & 0 \end{bmatrix}$$
(16.3.38)

4. In matrix form,

$$g = \begin{bmatrix} 1\\2\\3 \end{bmatrix}, \quad P^2 g = \begin{bmatrix} 2\\\frac{9}{8}\\\frac{3}{2} \end{bmatrix}$$
(16.3.39)

5. In matrix form,  $X_0$  has PDF  $f = \begin{bmatrix} \frac{1}{3} & \frac{1}{3} & \frac{1}{3} \end{bmatrix}$ , and  $X_2$  has PDF  $fP^2 = \begin{bmatrix} \frac{7}{12} & \frac{7}{24} & \frac{1}{8} \end{bmatrix}$ .

Let  $A = \{a, b\}$ . Find each of the following:

1. 
$$P_A$$
  
2.  $P_A^2$   
3.  $(P^2)_A$   
Proof  
1.  $P_A = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{1}{4} & 0 \end{bmatrix}$   
2.  $P_A^2 = \begin{bmatrix} \frac{3}{8} & \frac{1}{4} \\ \frac{1}{8} & \frac{1}{8} \end{bmatrix}$   
3.  $(P^2)_A = \begin{bmatrix} \frac{3}{8} & \frac{1}{4} \\ \frac{7}{5} & \frac{1}{5} \end{bmatrix}$ 

Find the invariant probability density function of  $\boldsymbol{X}$ 

Answer

Solving fP = f subject to the condition that f is a PDF gives  $f = \begin{bmatrix} \frac{8}{15} & \frac{4}{15} & \frac{3}{15} \end{bmatrix}$ 

Compute the  $\alpha$ -potential matrix  $R_{\alpha}$  for  $\alpha \in (0, 1)$ .

Answer

Computing  $R_{\alpha} = (I - \alpha P)^{-1}$  gives

$$R_{\alpha} = \frac{1}{(1-\alpha)(8+4\alpha+3\alpha^2)} \begin{bmatrix} 8 & 4\alpha & 3\alpha^2 \\ 2\alpha+6\alpha^2 & 8-4\alpha & 6\alpha-3\alpha^2 \\ 8\alpha & 4\alpha^2 & 8-4\alpha-\alpha^2 \end{bmatrix}$$
(16.3.40)

As a check on our work, note that the row sums are  $\frac{1}{1-\alpha}$ .

# The Two-State Chain

Perhaps the simplest, non-trivial Markov chain has two states, say  $S = \{0, 1\}$  and the transition probability matrix given below, where  $p \in (0, 1)$  and  $q \in (0, 1)$  are parameters.

$$P = \begin{bmatrix} 1-p & p \\ q & 1-q \end{bmatrix}$$
(16.3.41)

For  $n \in \mathbb{N}$  ,

$$P^{n} = \frac{1}{p+q} \begin{bmatrix} q+p(1-p-q)^{n} & p-p(1-p-q)^{n} \\ q-q(1-p-q)^{n} & p+q(1-p-q)^{n} \end{bmatrix}$$
(16.3.42)

Proof

The eigenvalues of *P* are 1 and 1 - p - q. Next,  $B^{-1}PB = D$  where

$$B = \begin{bmatrix} 1 & -p \\ 1 & q \end{bmatrix}, \quad D = \begin{bmatrix} 1 & 0 \\ 0 & 1-p-q \end{bmatrix}$$
(16.3.43)

Hence  $P^n = BD^n B^{-1}$ , which gives the expression above.

As  $n o \infty$  ,

$$P^{n} \to \frac{1}{p+q} \begin{bmatrix} q & p \\ q & p \end{bmatrix}$$
(16.3.44)

Proof

Note that 0 < p+q < 2 and so -1 < 1-(p+q) < 1 . Hence  $(1-p-q)^n \to 0$  as  $n \to \infty$  .

Open the simulation of the two-state, discrete-time Markov chain. For various values of p and q, and different initial states, run the simulation 1000 times. Compare the relative frequency distribution to the limiting distribution, and in particular, note the rate of convergence. Be sure to try the case p = q = 0.01

The only invariant probability density function for the chain is

$$f = \begin{bmatrix} \frac{q}{p+q} & \frac{p}{p+q} \end{bmatrix}$$
(16.3.45)

Proof

Let  $f = \begin{bmatrix} a & b \end{bmatrix}$ . The matrix equation fP = f leads to -pa + qb = 0 so  $b = a\frac{p}{q}$ . The condition a + b = 1 for f to be a PDF then gives  $a = \frac{q}{p+q}$ ,  $b = \frac{p}{p+q}$ .

For  $\alpha \in (0, 1)$ , the  $\alpha$ -potential matrix is

$$R_{\alpha} = \frac{1}{(p+q)(1-\alpha)} \begin{bmatrix} q & p \\ q & p \end{bmatrix} + \frac{1}{(p+q)^2(1-\alpha)} \begin{bmatrix} p & -p \\ -q & q \end{bmatrix}$$
(16.3.46)

Proof

In this case,  $R_{\alpha}$  can be computed directly as  $\sum_{n=0}^{\infty} \alpha^n P^n$  using geometric series.

In spite of its simplicity, the two state chain illustrates some of the basic limiting behavior and the connection with invariant distributions that we will study in general in a later section.

#### Independent Variables and Random Walks

Suppose that  $X = (X_0, X_1, X_2, ...)$  is a sequence of independent random variables taking values in a countable set S, and that  $(X_1, X_2, ...)$  are identically distributed with (discrete) probability density function f.

X is a Markov chain on S with transition probability matrix P given by P(x, y) = f(y) for  $(x, y) \in S \times S$ . Also, f is invariant for P. Proof

As usual, let  $\mathscr{F}_n = \sigma\{X_0, X_1, \dots, X_n\}$  for  $n \in \mathbb{N}$ . Since the sequence X is independent,

$$\mathbb{P}(X_{n+1} = y \mid \mathscr{F}_n) = \mathbb{P}(X_{n+1} = y) = f(y), \quad y \in S$$

$$(16.3.47)$$

Also,

$$fP(y) = \sum_{x \in S} f(x)P(x,y) = \sum_{x \in S} f(x)f(y) = f(y), \quad y \in S$$
 (16.3.48)

As a Markov chain, the process X is not very interesting, although of course it is very interesting in other ways. Suppose now that  $S = \mathbb{Z}$ , the set of integers, and consider the *partial sum process* (or *random walk*) Y associated with X:

$$Y_n = \sum_{i=0}^n X_i, \quad n \in \mathbb{N}$$
 (16.3.49)

 $m{Y}$  is a Markov chain on  $\mathbb{Z}$  with transition probability matrix Q given by Q(x, y) = f(y - x) for  $(x, y) \in \mathbb{Z} \times \mathbb{Z}$ . Proof

Again, let 
$$\mathscr{F}_n = \sigma\{X_0, X_1, \dots, X_n\}$$
 for  $n \in \mathbb{N}$ . Then also,  $\mathscr{F}_n = \sigma\{Y_0, Y_1, \dots, Y_n\}$  for  $n \in \mathbb{N}$ . Hence  

$$\mathbb{P}(Y_{n+1} = y \mid \mathscr{F}_n) = \mathbb{P}(Y_n + X_{n+1} = y \mid \mathscr{F}_n) = \mathbb{P}(Y_n + X_{n+1} = y \mid Y_n), \quad y \in \mathbb{Z}$$
(16.3.50)

since the sequence  $\boldsymbol{X}$  is independent. In particular,

$$\mathbb{P}(Y_{n+1} = y \mid Y_n = x) = \mathbb{P}(x + X_{n+1} = y \mid Y_n = x) = \mathbb{P}(X_{n+1} = y - x) = f(y - x), \quad (x, y) \in \mathbb{Z}^2$$
(16.3.51)

Thus the probability density function f governs the distribution of a step size of the random walker on  $\mathbb{Z}$ .

Consider the special case of the random walk on  $\mathbb Z$  with f(1) = p and f(-1) = 1 - p, where  $p \in (0, 1)$ .

1. Give the transition matrix Q explicitly.

2. Give  $Q^n$  explicitly for  $n \in \mathbb{N}$ .

Answer

1. Q(x,x-1)=1-p , Q(x,x+1)=p for  $x\in Z$  . 2. For  $k\in\{0,1,\ldots,n\}$ 

$$Q^{n}(x, x+2k-n) = \binom{n}{k} p^{k} (1-p)^{n-k}$$
(16.3.52)

This corresponds to k steps to the right and n - k steps to the left.

This special case is the *simple random walk* on  $\mathbb{Z}$ . When  $p = \frac{1}{2}$  we have the *simple, symmetric random walk*. The simple random walk on  $\mathbb{Z}$  is studied in more detail in the section on random walks on graphs. The simple symmetric random walk is studied in more detail in the chapter on Bernoulli Trials.

### **Doubly Stochastic Matrices**

A matrix P on S is *doubly stochastic* if it is nonnegative and if the row *and* columns sums are 1:

$$\sum_{u \in S} P(x, u) = 1, \ \sum_{u \in s} P(u, y) = 1, \quad (x, y) \in S \times S \tag{16.3.53}$$

Suppose that X is a Markov chain on a finite state space S with doubly stochastic transition matrix P. Then the uniform distribution on S is invariant. Proof

Constant functions are left invariant. Suppose that f(x) = c for  $x \in S$ . Then

$$fP(y) = \sum_{x \in S} f(x)P(x,y) = c \sum_{x \in S} P(x,y) = c, \quad y \in S$$
(16.3.54)

Hence if *S* is finite, the uniform PDF *f* given by f(x) = 1/#(S) for  $x \in S$  is invariant.

If P and Q are doubly stochastic matrices on S, then so is PQ.

Proof

For  $y\in S$  ,

$$\sum_{x \in S} PQ(x, y) = \sum_{x \in S} \sum_{z \in S} P(x, z)Q(z, y) = \sum_{z \in S} Q(z, y) \sum_{x \in S} P(x, z) = \sum_{z \in S} Q(z, y) = 1$$
(16.3.55)

The interchange of sums is valid since the terms are nonnegative.

It follows that if P is doubly stochastic then so is  $P^n$  for  $n \in \mathbb{N}$ .

Suppose that  $X = (X_0, X_1, ...)$  is the Markov chain with state space  $S = \{-1, 0, 1\}$  and with transition matrix

$$P = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} & 0\\ 0 & \frac{1}{2} & \frac{1}{2}\\ \frac{1}{2} & 0 & \frac{1}{2} \end{bmatrix}$$
(16.3.56)

1. Draw the state graph.

2. Show that P is doubly stochastic

3. Find  $P^2$ .

4. Show that the uniform distribution on S is the only invariant distribution for  $\boldsymbol{X}$ .

- 5. Suppose that  $X_0$  has the uniform distribution on S. For  $n \in \mathbb{N}$ , find  $\mathbb{E}(X_n)$  and  $\operatorname{var}(X_n)$ .
- 6. Find the lpha-potential matrix  $R_lpha$  for  $lpha\in(0,1).$

Proof

1. The edge set is 
$$E = \{(-1, -1), (-1, 0), (0, 0), (0, 1), (1, -1), (1, 1)\}$$

2. Just note that the row sums and the column sums are 1.

3. By matrix multiplication,

$$P^{2} = \begin{bmatrix} \frac{1}{4} & \frac{1}{2} & \frac{1}{4} \\ \frac{1}{4} & \frac{1}{4} & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{4} & \frac{1}{4} \end{bmatrix}$$
(16.3.57)

4. Let  $f = [p \ q \ r]$ . Solving the equation fP = f gives p = q = r. The requirement that f be a PDF then forces the common value to be  $\frac{1}{3}$ . 5. If  $X_0$  has the uniform distribution on S, then so does  $X_n$  for every  $n \in \mathbb{N}$ , so  $\mathbb{E}(X_n) = 0$  and  $\operatorname{var}(X_n) = \mathbb{E}(X_0^2) = \frac{2}{3}$ .

$$R_{\alpha} = (I - \alpha P)^{-1} = \frac{1}{(1 - \alpha)(4 - 2\alpha + \alpha^2)} \begin{bmatrix} 4 - 4a + a^2 & 2a - a^2 & a^2 \\ a^2 & 4 - 4a + a^2 & 2a - a^2 \\ 2a - a^2 & a^2 & 4 - 4a + a^2 \end{bmatrix}$$
(16.3.58)

Recall that a matrix M indexed by a countable set S is *symmetric* if M(x, y) = M(y, x) for all  $x, y \in S$ .

If  $\boldsymbol{P}$  is a symmetric, stochastic matrix then  $\boldsymbol{P}$  is doubly stochastic.

Proof

6.

This is trivial since

$$\sum_{x \in S} P(x, y) = \sum_{x \in S} P(y, x) = 1, \quad y \in S$$
 (16.3.59)

The converse is not true. The doubly stochastic matrix in the exercise above is not symmetric. But since a symmetric, stochastic matrix on a finite state space is doubly stochastic, the uniform distribution is invariant.

Suppose that  $X = (X_0, X_1, ...)$  is the Markov chain with state space  $S = \{-1, 0, 1\}$  and with transition matrix

$$P = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \frac{1}{4} & \frac{3}{4} \\ 0 & \frac{3}{4} & \frac{1}{4} \end{bmatrix}$$
(16.3.60)

1. Draw the state graph.

2. Show that P is symmetric

3. Find  $P^2$ .

4. Find all invariant probability density functions for  $\boldsymbol{X}$ .

5. Find the  $\alpha$ -potential matrix  $R_{\alpha}$  for  $\alpha \in (0, 1)$ .

Proof

1. The edge set is  $E = \{(-1, -1), (0, 0), (0, 1), (1, 0), (1, 1)\}$ 

2. Just note that P is symmetric with respect to the main diagonal.

3. By matrix multiplication,

$$P^{2} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \frac{5}{8} & \frac{3}{8} \\ 0 & \frac{3}{8} & \frac{5}{8} \end{bmatrix}$$
(16.3.61)

4. Let  $f = \begin{bmatrix} p & q & r \end{bmatrix}$ . Solving the equation fP = f gives simply r = q. The requirement that f be a PDF forces p = 1 - 2q. Thus the invariant PDFs are  $f = \begin{bmatrix} 1 - 2q & q & q \end{bmatrix}$  where  $q \in \begin{bmatrix} 0, \frac{1}{2} \end{bmatrix}$ . The special case  $q = \frac{1}{3}$  gives the uniform distribution on S.

5.

$$R_{\alpha} = (I - \alpha P)^{-1} = \frac{1}{2(1 - \alpha)^{2}(2 + \alpha)} \begin{bmatrix} 4 - 2\alpha - 2\alpha^{2} & 0 & 0\\ 0 & 4 - 5\alpha + \alpha^{2} & 3\alpha - 3\alpha^{2}\\ 0 & 3\alpha - 3\alpha^{2} & 4 - 5\alpha + \alpha^{2} \end{bmatrix}$$
(16.3.62)

#### **Special Models**

The Markov chains in the following exercises model interesting processes that are studied in separate sections.

Read the introduction to the Ehrenfest chains.

Read the introduction to the Bernoulli-Laplace chain.

Read the introduction to the reliability chains.

Read the introduction to the branching chain.

Read the introduction to the queuing chains.

Read the introduction to random walks on graphs.

Read the introduction to birth-death chains.

## 16.4: Transience and Recurrence for Discrete-Time Chains

The study of discrete-time Markov chains, particularly the limiting behavior, depends critically on the random times between visits to a given state. The nature of these random times leads to a fundamental dichotomy of the states.

### **Basic Theory**

As usual, our starting point is a probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ , so that  $\Omega$  is the sample space,  $\mathscr{F}$  the  $\sigma$ -algebra of events, and  $\mathbb{P}$  the probability measure on  $(\Omega, \mathscr{F})$ . Suppose now that  $\mathbf{X} = (X_0, X_1, X_2, ...)$  is a (homogeneous) discrete-time Markov chain with (countable) state space S and transition probability matrix P. So by definition,

$$P(x,y) = \mathbb{P}(X_{n+1} = y \mid X_n = x)$$
(16.4.1)

for  $x, y \in S$  and  $n \in \mathbb{N}$ . Let  $\mathscr{F}_n = \sigma\{X_0, X_1, \ldots, X_n\}$ , the  $\sigma$ -algebra of events defined by the chain up to time  $n \in \mathbb{N}$ , so that  $\mathfrak{F} = (\mathscr{F}_0, \mathscr{F}_1, \ldots)$  is the natural filtration associated with X.

#### **Hitting Times and Probabilities**

Let *A* be a nonempty subset of *S*. Recall that the *hitting time* to *A* is the random variable that gives the first positive time that the chain is in *A*:

$$\tau_A = \min\{n \in \mathbb{N}_+ : X_n \in A\} \tag{16.4.2}$$

Since the chain may *never* enter A, the random variable  $\tau_A$  takes values in  $\mathbb{N}_+ \cup \{\infty\}$  (recall our convention that the minimum of the empty set is  $\infty$ ). Recall also that  $\tau_A$  is a stopping time for X. That is,  $\{\tau_A = n\} \in \mathscr{F}_n$  for  $n \in \mathbb{N}_+$ . Intuitively, this means that we can tell if  $\tau_A = n$  by observing the chain up to time n. This is clearly the case, since explicitly

$$\{ au_A = n\} = \{X_1 
otin A, \dots, X_{n-1} 
otin A, X_n \in A\}$$
 (16.4.3)

When  $A = \{x\}$  for  $x \in S$ , we will simplify the notation to  $\tau_x$ . This random variable gives the first positive time that the chain is in state x. When the chain enters a set of states A for the first time, the chain must visit some state in A for the first time, so it's clear that

$$au_A = \min\{ au_x : x \in A\}, \quad A \subseteq S$$

$$(16.4.4)$$

Next we define two functions on *S* that are related to the hitting times.

 $\begin{array}{l} \text{For } x\in S, A\subseteq S \text{ (nonempty), and } n\in \mathbb{N}_+ \text{ define}\\ 1.\ H_n(x,A)=\mathbb{P}(\tau_A=n\mid X_0=x)\\ 2.\ H(x,A)=\mathbb{P}(\tau_A<\infty\mid X_0=x)\\ \text{So } H(x,A)=\sum_{n=1}^\infty H_n(x,A). \end{array}$ 

Note that  $n \mapsto H_n(x, A)$  is the probability density function of  $\tau_A$ , given  $X_0 = x$ , except that the density function may be *defective* in the sense that the sum H(x, A) may be less than 1, in which case of course,  $1 - H(x, A) = \mathbb{P}(\tau_A = \infty | X_0 = x)$ . Again, when  $A = \{y\}$ , we will simplify the notation to  $H_n(x, y)$  and H(x, y), respectively. In particular, H(x, x) is the probability, starting at x, that the chain eventually returns to x. If  $x \neq y$ , H(x, y) is the probability, starting at x, that the chain eventually returns to x. If  $x \neq y$ , H(x, y) is the probability, starting at x, that the chain eventually returns to x. If  $x \neq y$ , H(x, y) is the probability, starting at x, that the chain eventually returns of x. If  $x \neq y$ , H(x, y) is the probability, starting at x, that the chain eventually returns of x. If  $x \neq y$ , H(x, y) is the probability, starting at x, that the chain eventually reaches y. Just knowing when H(x, y) is 0, positive, and 1 will turn out to be of considerable importance in the overall structure and limiting behavior of the chain. As a function on  $S^2$ , we will refer to H as the *hitting matrix* of X. Note however, that unlike the transition matrix P, we do not have the structure of a kernel. That is,  $A \mapsto H(x, A)$  is not a measure, so in particular, it is generally not true that  $H(x, A) = \sum_{y \in A} H(x, y)$ . The same remarks apply to  $H_n$  for  $n \in \mathbb{N}_+$ . However, there are interesting relationships between the transition matrix and the hitting matrix.

H(x,y)>0 if and only if  $P^n(x,y)>0$  for some  $n\in\mathbb{N}_+$  .

### Proof

Note that  $\{X_n = y\} \subseteq \{\tau_y < \infty\}$  for all  $n \in \mathbb{N}_+$ , and  $\{\tau_y < \infty\} = \{X_k = y \text{ for some } k \in \mathbb{N}_+\}$ . From the increasing property of probability and Boole's inequality it follows that for each  $n \in \mathbb{N}_+$ ,

$$P^{n}(x,y) \le H(x,y) \le \sum_{k=1}^{\infty} P^{k}(x,y)$$
 (16.4.5)

The following result gives a basic relationship between the sequence of hitting probabilities and the sequence of transition probabilities.

Suppose that  $(x, y) \in S^2$ . Then

$$P^n(x,y) = \sum_{k=1}^n H_k(x,y) P^{n-k}(y,y), \quad n \in \mathbb{N}_+$$
 (16.4.6)

Proof

This result follows from conditioning on  $\tau_y$ . Starting in state x, the chain is in state y at time n if and only if the chain hits y for the first time at some previous time k, and then returns to y in the remaining n - k steps. More formally,

$$P^{n}(x,y) = \mathbb{P}(X_{n} = y \mid X_{0} = x) = \sum_{k=0}^{\infty} \mathbb{P}(X_{n} = y \mid \tau_{y} = k, X_{0} = x) \mathbb{P}(\tau_{y} = k \mid X_{0} = x)$$
(16.4.7)

But the event  $\tau_y = k$  implies  $X_k = y$  and is in  $\mathscr{F}_k$ . Hence by the Markov property,

$$\mathbb{P}(X_n = y \mid \tau_y = k, X_0 = x) = \mathbb{P}(X_n = y \mid X_k = y, \tau_y = k, X_0 = x) = \mathbb{P}(X_n = y \mid X_k = y) = P^k(x, y)$$
(16.4.8)

Of course, by definition,  $\mathbb{P}( au_y=k \mid X_0=x) = H_k(x,y)\,$  , so the result follows by substitution.

Suppose that  $x \in S$  and  $A \subseteq S$ . Then

$$egin{aligned} 1.\ H_{n+1}(x,A) &= \sum_{y
otin A} P(x,y) H_n(y,A) ext{ for } n\in\mathbb{N}_+ \ 2.\ H(x,A) &= P(x,A) + \sum_{y
otin A} P(x,y) H(y,A) \end{aligned}$$

Proof

These results follow form conditioning on  $X_1$ .

1. Starting in state x, the chain first enters A at time n+1 if and only if the chain goes to some state  $y \notin A$  at time 1, and then from state y, first enters A in n steps.

$$H_{n+1}(x,A) = \mathbb{P}( au_A = n+1 \mid X_0 = x) = \sum_{y \in S} \mathbb{P}( au_A = n+1 \mid X_0 = x, X_1 = y) \mathbb{P}(X_1 = y \mid X_0 = x)$$
 (16.4.9)

But  $\mathbb{P}(\tau_A = n+1 \mid X_0 = x, X_1 = y) = 0$  for  $y \in A$ . By the Markov and time homogeneous properties,  $\mathbb{P}(\tau_A = n+1 \mid X_0 = x, X_1 = y) = \mathbb{P}(\tau_A = n \mid X_0 = y) = H_n(x, A)$  for  $y \notin A$ . Of course  $\mathbb{P}(X_1 = y \mid X_0 = x) = P(x, y)$ . So the result follows by substitution.

2. Starting in state x, the chain eventually enters A if and only if it either enters A at the first step, or moves to some other state  $y \notin A$  at the first step, and then eventually enters A from y.

$$H(x,A) = \mathbb{P}( au_A < \infty \mid X_0 = x) = \sum_{y \in S} \mathbb{P}( au_A < \infty \mid X_1 = y, X_0 = x) \mathbb{P}(X_1 = y \mid X_0 = x)$$
(16.4.10)

 $\begin{array}{l} \text{But } \mathbb{P}(\tau_A < \infty \mid X_1 = y, X_0 = x) = 1 \quad \text{for } y \in A. \text{ By the Markov and homogeneous properties,} \\ \mathbb{P}(\tau_A < \infty \mid X_1 = y, X_0 = x) = \mathbb{P}(\tau_A < \infty \mid X_0 = y) = H(y, A) \quad \text{ for } y \notin A. \text{ Substituting we have } H(y, A) \\ \end{array}$ 

$$H(x,A) = \sum_{y \in A} P(x,y) + \sum_{y \notin A} P(x,y)H(y,A) = P(x,A) + \sum_{y \notin A} P(x,y)H(y,A)$$
(16.4.11)

The following definition is fundamental for the study of Markov chains.

Let  $x \in S$ .

1. State *x* is *recurrent* if H(x, x) = 1.

2. State *x* is *transient* if H(x, x) < 1.

Thus, starting in a recurrent state, the chain will, with probability 1, eventually return to the state. As we will see, the chain will return to the state infinitely often with probability 1, and the times of the visits will form the arrival times of a renewal process. This will turn out to be the critical observation in the study of the limiting behavior of the chain. By contrast, if the chain starts in a transient state, then there is a positive probability that the chain will never return to the state.

### **Counting Variables and Potentials**

Again, suppose that A is a nonempty set of states. A natural complement to the hitting time to A is the *counting variable* that gives the number of visits to A (at positive times). Thus, let

$$N_A = \sum_{n=1}^{\infty} \mathbf{1}(X_n \in A)$$
 (16.4.12)

Note that  $N_A$  takes value in  $\mathbb{N} \cup \{\infty\}$ . We will mostly be interested in the special case  $A = \{x\}$  for  $x \in S$ , and in this case, we will simplify the notation to  $N_x$ .

Let  $G(x,A) = \mathbb{E}(N_A \mid X_0 = x) ~~ ext{for}~ x \in S$  and  $A \subseteq S$  . Then G is a kernel on S and

$$G(x,A) = \sum_{n=1}^{\infty} P^n(x,A)$$
(16.4.13)

Proof

Note that

$$G(x,A) = \mathbb{E}\left(\sum_{n=1}^{\infty} \mathbf{1}(X_n \in A) \ \Big| \ X_0 = x
ight) = \sum_{n=1}^{\infty} \mathbb{P}(X_n \in A \ | \ X_0 = x) = \sum_{n=1}^{\infty} P^n(x,A)$$
(16.4.14)

The interchange of sum and expected value is justified since the terms are nonnegative. For fixed  $x \in S$ ,  $A \mapsto G(x, A)$  is a positive measure on S since  $A \mapsto P^n(x, A)$  is a probability measure on S for each  $n \in \mathbb{N}_+$ . Note also that  $A \mapsto N_A$  is a random, counting measure on S and hence  $A \mapsto G(x, A)$  is a (deterministic) positive measure on S.

Thus G(x, A) is the expected number of visits to A at positive times. As usual, when  $A = \{y\}$  for  $y \in S$  we simplify the notation to G(x, y), and then more generally we have  $G(x, A) = \sum_{y \in A} G(x, y)$  for  $A \subseteq S$ . So, as a matrix on S,  $G = \sum_{n=1}^{\infty} P^n$ . The matrix G is closely related to the potential matrix R of X, given by  $R = \sum_{n=0}^{\infty} P^n$ . So R = I + G, and R(x, y) gives the expected number of visits to  $y \in S$  at all times (not just positive times), starting at  $x \in S$ . The matrix G is more useful for our purposes in this section.

The distribution of  $N_y$  has a simple representation in terms of the hitting probabilities. Note that because of the Markov property and time homogeneous property, whenever the chain reaches state y, the future behavior is independent of the past and is stochastically the same as the chain starting in state y at time 0. This is the critical observation in the proof of the following theorem.

If  $x, y \in S$  then 1.  $\mathbb{P}(N_y = 0 \mid X_0 = x) = 1 - H(x, y)$ 2.  $\mathbb{P}(N_y = n \mid X_0 = x) = H(x, y)[H(y, y)]^{n-1}[1 - H(y, y)]$  for  $n \in \mathbb{N}_+$ Proof

Figure 16.4.1: Visits to state y starting in state x

The essence of the proof is illustrated in the graphic above. The thick lines are intended as reminders that these are not one step transitions, but rather represent all paths between the given vertices. Note that in the special case that x = y we have

$$\mathbb{P}(N_x = n \mid X_0 = x) = [H(x, x)]^n [1 - H(x, x)], \quad n \in \mathbb{N}$$
 (16.4.15)

In all cases, the counting variable  $N_y$  has essentially a geometric distribution, but the distribution may well be *defective*, with some of the probability mass at  $\infty$ . The behavior is quite different depending on whether y is transient or recurrent.

If 
$$x, y \in S$$
 and  $y$  is transient then  
1.  $\mathbb{P}(N_y < \infty \mid X_0 = x) = 1$   
2.  $G(x, y) = H(x, y)/[1 - H(y, y)]$   
3.  $H(x, y) = G(x, y)/[1 + G(y, y)]$   
Proof

1. If *y* is transient then H(y, y) < 1. Hence using the result above and geometric series,

$$\mathbb{P}(N_y \in \mathbb{N}_+ \mid X_0 = x) = \sum_{n=1}^{\infty} \mathbb{P}(N_y = n \mid X_0 = x) = H(x, y)[1 - H(y, y)] \sum_{n=1}^{\infty} [H(y, y)]^{n-1} = H(x, y) \quad (16.4.16)$$

Hence

$$\mathbb{P}(N_y < \infty \mid X_0 = x) \quad = \mathbb{P}(N_y \in \mathbb{N} \mid X_0 = x) = \mathbb{P}(N_y = 0 \mid X_0 = x) + \mathbb{P}(N_y \in \mathbb{N}_+ \mid X_0 = x) \ = [1 - H(x,y)] + H(x,y) = 1$$

2. Using the derivative of the geometric series,

$$egin{aligned} G(x,y) &= \mathbb{E}(N_y \mid X_0 = x) = \sum_{n=1}^\infty n \mathbb{P}(N_y = n \mid X_0 = x) \ &= H(x,y)[1-H(y,y)] \sum_{n=1}^\infty n [H(y,y)]^{n-1} = rac{H(x,y)}{1-H(y,y)} \end{aligned}$$

3. From (b), G(y, y) = H(y, y)/[1 - H(y, y)] so solving for H(y, y) gives H(y, y) = G(y, y)/[1 + G(y, y)]. Substituting this back into (b) gives G(x, y) = H(x, y)[1 + G(y, y)].

if  $x, y \in S$  and y is recurrent then

 $\begin{array}{l} 1. \ \mathbb{P}(N_y = 0 \mid X_0 = x) = 1 - H(x,y) \ \, \text{and} \ \mathbb{P}(N_y = \infty \mid X_0 = x) = H(x,y) \\ 2. \ G(x,y) = 0 \ \text{if} \ H(x,y) = 0 \ \text{and} \ G(x,y) = \infty \ \text{if} \ H(x,y) > 0 \\ 3. \ \mathbb{P}(N_y = \infty \mid X_0 = y) = 1 \ \, \text{and} \ G(y,y) = \infty \end{array}$ 

## Proof

1. If y is recurrent, H(y, y) = 1 and so from the result above,  $\mathbb{P}(N_y = n \mid X_0 = x) = 0$  for all  $n \in \mathbb{N}_+$ . Hence  $\mathbb{P}(N_y = \infty \mid X_0 = x) = 1 - \mathbb{P}(N_y = 0 \mid X_0 = x) = 1 - H(x, y)$ . 2. If H(x, y) = 0 then  $\mathbb{P}(N_y = 0 \mid X_0 = x) = 1$ , so  $\mathbb{E}(N_y \mid X_0 = x) = 0$ . If H(x, y) > 0 then  $\mathbb{P}(N_y = \infty \mid X_0 = x) > 0$  so  $\mathbb{E}(N_y \mid X_0 = x) = \infty$ . 3. From the result above,  $\mathbb{P}(N_y = n \mid X_0 = y) = 0$  for all  $n \in \mathbb{N}$ , so  $\mathbb{P}(N_y = \infty \mid X_0 = y) = 1$ .

Note that there is an invertible relationship between the matrix H and the matrix G; if we know one we can compute the other. In particular, we can characterize the transience or recurrence of a state in terms of G. Here is our summary so far:

Let  $x \in S$ .

- 1. State x is transient if and only if H(x, x) < 1 if and only if  $G(x, x) < \infty$ .
- 2. State *x* is recurrent if and only if H(x, x) = 1 if and only if  $G(x, x) = \infty$ .

Of course, the classification also holds for the potential matrix R = I + G. That is, state  $x \in S$  is transient if and only if  $R(x, x) < \infty$  and state x is recurrent if and only if  $R(x, x) = \infty$ .

#### Relations

The hitting probabilities suggest an important relation on the state space S.

For  $(x, y) \in S^2$ , we say that *x leads to y* and we write  $x \to y$  if either x = y or H(x, y) > 0.

It follows immediately from the result above that  $x \to y$  if and only if  $P^n(x, y) > 0$  for some  $n \in \mathbb{N}$ . In terms of the state graph of the chain,  $x \to y$  if and only if x = y or there is a directed path from x to y. Note that the *leads to* relation is *reflexive* by definition:  $x \to x$  for every  $x \in S$ . The relation has another important property as well.

The *leads to* relation is *transitive*: For  $x, y, z \in S$ , if  $x \to y$  and  $y \to z$  then  $x \to z$ .

Proof

 $\begin{array}{ll} \text{If} \quad x \to y \quad \text{and} \quad y \to z, \quad \text{then} \quad \text{there} \quad \text{exist} \quad j, \ k \in N \quad \text{such} \quad \text{that} \quad P^j(x,y) > 0 \quad \text{and} \quad P^k(y,z) > 0. \\ P^{j+k}(x,z) \geq P^j(x,y) P^k(y,z) > 0 \quad \text{so} \ x \to z. \end{array}$ 

The *leads to* relation naturally suggests a couple of other definitions that are important.

Suppose that  $A \subseteq S$  is nonempty.

- 1. *A* is *closed* if  $x \in A$  and  $x \to y$  implies  $y \in A$ .
- 2. *A* is *irreducible* if *A* is closed and has no proper closed subsets.

Suppose that  $A \subseteq S$  is closed. Then

- 1.  $P_A$ , the restriction of P to  $A \times A$ , is a transition probability matrix on A.
- 2. X restricted to A is a Markov chain with transition probability matrix  $P_A$ .

3.  $(P^n)_A=(P_A)^n ext{ for } n\in\mathbb{N}.$ 

Proof

- 1. If  $x \in A$  and  $y \notin A$ , then x does not lead to y so in particular P(x, y) = 0. It follows that  $\sum_{y \in A} P(x, y) = 1$  for  $x \in A$  so  $P_A$  is a transition probability matrix.
- 2. This follows from (a). If the chain starts in *A*, then the chain remains in *A* for all time, and of course, the Markov property still holds.
- 3. Again, this follows from (a).

Of course, the entire state space S is closed by definition. If it is also irreducible, we say the Markov chain X itself is *irreducible*. Recall that for a nonempty subset A of S and for  $n \in \mathbb{N}$ , the notation  $P_A^n$  refers to  $(P_A)^n$  and not  $(P^n)_A$ . In general, these are not the same, and in fact for  $x, y \in A$ ,

$$P^n_A(x,y) = \mathbb{P}(X_1 \in A, \dots, X_{n-1} \in A, X_n = y \mid X_0 = x)$$
 (16.4.17)

the probability of going from x to y in n steps, remaining in A all the while. But if A is closed, then as noted in part (c), this is just  $P^{n}(x, y)$ .

Suppose that *A* is a nonempty subset of *S*. Then  $cl(A) = \{y \in S : x \to y \text{ for some } x \in A\}$  is the smallest closed set containing *A*, and is called the *closure* of *A*. That is,

1. cl(A) is closed.

2.  $A \subseteq \operatorname{cl}(A)$ .

3. If *B* is closed and  $A \subseteq B$  then  $\operatorname{cl}(A) \subseteq B$ 

Proof

- 1. Suppose that  $x \in cl(A)$  and that  $x \to y$ . Then there exists  $a \in A$  such that  $a \to x$ . By the transitive property,  $a \to y$  and hence  $y \in cl(A)$ .
- 2. If  $x \in A$  then  $x \to x$  so  $x \in cl(A)$ .
- 3. Suppose that *B* is closed and that  $A \subseteq B$ . If  $x \in cl(A)$ , then there exists  $a \in A$  such that  $a \to x$ . Hence  $a \in B$  and  $a \to x$ . Since *B* is closed, it follows that  $x \in B$ . Hence  $cl(A) \subseteq B$ .

Recall that for a fixed positive integer k,  $P^k$  is also a transition probability matrix, and in fact governs the *k*-step Markov chain  $(X_0, X_k, X_{2k}, ...)$ . It follows that we could consider the *leads to* relation for this chain, and all of the results above would still hold (relative, of course, to the *k*-step chain). Occasionally we will need to consider this relation, which we will denote by  $\rightarrow$ , particularly in

our study of periodicity.

Suppose that  $j, \, k \in \mathbb{N}_+$  . If  $x \stackrel{
ightarrow}{\to} y$  and  $j \mid k$  then  $x \stackrel{
ightarrow}{\to} y.$ 

Proof

If  $x \xrightarrow{k} y$  then there exists  $n \in \mathbb{N}$  such that  $P^{nk}(x, y) > 0$ . If  $j \mid k$ , there exists  $m \in \mathbb{N}_+$  such that k = mj. Hence  $P^{nmj}(x, y) > 0$  so  $x \xrightarrow{j} y$ .

By combining the *leads* to relation  $\rightarrow$  with its inverse, the *comes from* relation  $\leftarrow$ , we can obtain another very useful relation.

For  $(x, y) \in S^2$ , we say that x to and from y and we write  $x \leftrightarrow y$  if  $x \rightarrow y$  and  $y \rightarrow x$ .

By definition, this relation is *symmetric*: if  $x \leftrightarrow y$  then  $y \leftrightarrow x$ . From our work above, it is also reflexive and transitive. Thus, the *to and from* relation is an equivalence relation. Like all equivalence relations, it partitions the space into mutually disjoint *equivalence classes*. We will denote the equivalence class of a state  $x \in S$  by

$$[x] = \{y \in S : x \leftrightarrow y\} \tag{16.4.18}$$

Thus, for any two states  $x, y \in S$ , either [x] = [y] or  $[x] \cap [y] = \emptyset$ , and moreover,  $\bigcup_{x \in S} [x] = S$ .

Figure 16.4.2: The equivalence relation partitions S into mutually disjoint equivalence classes

Two negative results:

1. A closed set is not necessarily an equivalence class.

2. An equivalence class is not necessarily closed.

Example

Consider the trivial Markov chain with state space  $S = \{0, 1\}$  and transition matrix  $P = \begin{bmatrix} 0 & 1 \\ 0 & 1 \end{bmatrix}$ . So state 0 leads deterministically to 1 in one step, while state 1 is absorbing. For the *leads to* relation, the only relationships are  $0 \rightarrow 0, 0 \rightarrow 1$ , and  $1 \rightarrow 1$ . Thus, the equivalence classes are  $\{0\}$  and  $\{1\}$ .

1. The entire state space S is closed, but is not an equivalence class.

2.  $\{0\}$  is an equivalence class but is not closed.

On the other hand, we have the following result:

If  $A \subseteq S$  is irreducible, then A is an equivalence class.

Proof

Fix  $x \in A$  (recall that closed sets are nonempty by definition). Since A is closed it follows that  $[x] \subseteq A$ . Since A is irreducible, cl(y) = A for each  $y \in A$  and in particular, cl(x) = A. It follows that  $x \leftrightarrow y$  for each  $y \in A$ . Hence  $A \subseteq [x]$ .

The *to and from* equivalence relation is very important because many interesting state properties turn out in fact to be *class properties*, shared by all states in a given equivalence class. In particular, the recurrence and transience properties are class properties.

#### **Transient and Recurrent Classes**

Our next result is of fundamental importance: a recurrent state can only lead to other recurrent states.

If x is a recurrent state and  $x \to y$  then y is recurrent and H(x, y) = H(y, x) = 1.

Proof

The result trivially holds if x = y, so we assume  $x \neq y$ . Let  $\alpha(x, y)$  denote the probability, starting at x, that the chain reaches y without an intermediate return to x. It must be the case that  $\alpha(x, y) > 0$  since  $x \to y$ . In terms of the graph of X, if there is a path from x to y, then there is a path from x to y without cycles. Starting at x, the chain could fail to return to x by first reaching y without an intermediate return to x, and then from y never reaching x. From the Markov and time homogeneous properties, it follows that  $1 - H(x, x) \ge \alpha(x, y)[1 - H(y, x)] \ge 0$ . But H(x, x) = 1 so it follows that H(y, x) = 1. So we now know that there exist positive integers j, k such that  $P^j(x, y) > 0$  and  $P^k(y, x) > 0$ . Hence for every  $n \in \mathbb{N}$ ,

$$P^{j+k+n}(y,y) \ge P^k(y,x)P^n(x,x)P^j(x,y)$$
 (16.4.19)

Recall that  $G(x, x) = \infty$  since x is recurrent. Thus, summing over n in the displayed equation gives  $G(y, y) = \infty$ . Hence y is recurrent. Finally, reversing the roles of x and y, if follows that H(x, y) = 1

From the last theorem, note that if x is recurrent, then all states in [x] are also recurrent. Thus, for each equivalence class, either all states are transient or all states are recurrent. We can therefore refer to *transient or recurrent classes* as well as states.

If A is a recurrent equivalence class then A is irreducible.

### Proof

Suppose that  $x \in A$  and that  $x \to y$ . Since x is recurrent, y is also recurrent and  $y \to x$ . Hence  $x \leftrightarrow y$  and so  $y \in A$  since A is an equivalence class. Suppose that  $B \subseteq A$  is closed. Since B is nonempty by definition, there exists  $x \in B$  and so  $x \in A$  also. For every  $y \in A$ ,  $x \leftrightarrow y$  so  $y \in B$  since B is closed. Thus A = B so A is irreducible.

If A is finite and closed then A has a recurrent state.

Proof

Fix  $x \in A$ . Since A is closed, it follows that  $\mathbb{P}(N_A = \infty | X_0 = x) = 1$ . Since A is finite, it follows that  $\mathbb{P}(N_y = \infty | X_0 = x) > 0$  for some  $y \in A$ . But then y is recurrent.

If A is finite and irreducible then A is a recurrent equivalence class.

Proof

Note that A is an equivalence class by a result above, and A has a recurrent state by previous result. It follows that all states in A are recurrent.

Thus, the Markov chain X will have a collection (possibly empty) of recurrent equivalence classes  $\{A_j : j \in J\}$  where J is a countable index set. Each  $A_j$  is irreducible. Let B denote the set of all transient states. The set B may be empty or may consist of a number of equivalence classes, but the class structure of B is usually not important to us. If the chain starts in  $A_j$  for some  $j \in J$  then the chain remains in  $A_j$  forever, visiting each state infinitely often with probability 1. If the chain starts in B, then the chain may stay in B forever (but only if B is infinite) or may enter one of the recurrent classes  $A_j$ , never to escape. However, in either case, the chain will visit a given transient state only finitely many time with probability 1. This basic structure is known as the *canonical decomposition* of the chain, and is shown in graphical form below. The edges from B are in gray to indicate that these transitions may not exist.

Figure 16.4.3: The canonical decomposition of the state space

Staying Probabilities and a Classification Test

Suppose that A is a proper subset of S. Then

1. 
$$P^n_A(x,A) = \mathbb{P}(X_1 \in A, X_2 \in A, \dots, X_n \in A \mid X_0 = x) ~~ ext{for}~ x \in A$$

2. 
$$\lim_{n o \infty} P^n_A(x,A) = \mathbb{P}(X_1 \in A, X_2 \in A \dots \mid X_0 = x) ~~ ext{for}~ x \in A$$

Proof

Recall that  $P_A^n$  means  $(P_A)^n$  where  $P_A$  is the restriction of P to  $A \times A$ .

- 1. This is a consequence of the Markov property, and is the probability that the chain stays in A at least through time n, starting in  $x \in A$ .
- 2. This follows from (a) and the continuity theorem for decreasing events. This is the probability that the chain stays in *A* forever, starting in  $x \in A$ .

Let  $g_A$  denote the function defined by part (b), so that

$$g_A(x) = \mathbb{P}(X_1 \in A, X_2 \in A, \dots \mid X_0 = x), \quad x \in A$$
 (16.4.20)

The *staying probability function*  $g_A$  is an interesting complement to the hitting matrix studied above. The following result characterizes this function and provides a method that can be used to compute it, at least in some cases.

For  $A \subset S$ ,  $g_A$  is the largest function on A that takes values in [0, 1] and satisfies  $g = P_A g$ . Moreover, either  $g_A = \mathbf{0}_A$  or  $\sup\{g_A(x) : x \in A\} = 1$ .

### Proof

Note that  $P_A^{n+1} \mathbf{1}_A = P_A P_A^n \mathbf{1}_A$  for  $n \in \mathbb{N}$ . Taking the limit as  $n \to \infty$  and using the bounded convergence theorem gives  $g_A = P_A g_A$ . Suppose now that g is a function on A that takes values in [0, 1] and satisfies  $g = P_A g$ . Then  $g \leq \mathbf{1}_A$  and hence  $g \leq P_A^n \mathbf{1}_A$  for all  $n \in \mathbb{N}$ . Letting  $n \to \infty$  it follows that  $g \leq g_A$ . Next, let  $c = \sup\{g_A(x) : x \in A\}$ . Then  $g_A \leq c \mathbf{1}_A$  and hence  $g_A \leq c P_A^n \mathbf{1}_A$  for each  $n \in \mathbb{N}$ . Letting  $n \to \infty$  gives  $g_A \leq c g_A$ . It follows that either  $g_A = \mathbf{0}_A$  or c = 1.

Note that the characterization in the last result includes a *zero-one law* of sorts: either the probability that the chain stays in A forever is 0 for every initial state  $x \in A$ , or we can find states in A for which the probability is arbitrarily close to 1. The next two results explore the relationship between the staying function and recurrence.

Suppose that X is an irreducible, recurrent chain with state space S. Then  $g_A = \mathbf{0}_A$  for every proper subset A of S.

#### Proof

Fix  $y \notin A$  and note that  $0 \leq g_A(x) \leq 1 - H(x, y)$  for every  $x \in A$ . But H(x, y) = 1 since the chain is irreducible and recurrent. Hence  $g_A(x) = 0$  for  $x \in A$ .

Suppose that X is an irreducible Markov chain with state space S and transition probability matrix P. If there exists a state x such that  $g_A = \mathbf{0}_A$  where  $A = S \setminus \{x\}$ , then X is recurrent.

#### Proof

With *A* as defined above, note that  $1 - H(x, x) = \sum_{y \in A} P(x, y)g_A(y)$ . Hence H(x, x) = 1, so *x* is recurrent. Since the *X* is irreducible, it follows that *X* is recurrent.

More generally, suppose that X is a Markov chain with state space S and transition probability matrix P. The last two theorems can be used to test whether an irreducible equivalence class C is recurrent or transient. We fix a state  $x \in C$  and set  $A = C \setminus \{x\}$ . We then try to solve the equation  $g = P_A g$  on A. If the only solution taking values in [0, 1] is  $\mathbf{0}_A$ , then the class C is recurrent by the previous result. If there are nontrivial solutions, then C is transient. Often we try to choose x to make the computations easy.

#### Computing Hitting Probabilities and Potentials

We now know quite a bit about Markov chains, and we can often classify the states and compute quantities of interest. However, we do not yet know how to compute:

- G(x, y) when x and y are transient
- H(x, y) when x is transient and y is transient or recurrent.

These problems are related, because of the general inverse relationship between the matrix H and the matrix G noted in our discussion above. As usual, suppose that X is a Markov chain with state space S, and let B denote the set of transient states. The next result shows how to compute  $G_B$ , the matrix G restricted to the transient states. Recall that the values of this matrix are finite.

 $G_B$  satisfies the equation  $G_B = P_B + P_B G_B$  and is the smallest nonnegative solution. If B is finite then  $G_B = (I_B - P_B)^{-1} P_B$ . Proof

First note the  $(P^n)_B = (P_B)^n$  since a path between two transient states can only pass through other transient states. Thus  $G_B = \sum_{n=1}^{\infty} P_B^n$ . From the monotone convergence theorem it follows that  $P_B G_B = G_B - P_B$ . Suppose now that U is a nonnegative matrix on B satisfying  $U = P_B + P_B U$ . Then  $U = \sum_{k=1}^n P_B^k + P_B^{n+1}U$  for each  $n \in \mathbb{N}_+$ . Hence  $U \ge \sum_{k=1}^n P_B^k$  for every  $n \in \mathbb{N}_+$  and therefore  $U \ge G_B$ . It follows that  $(I_B - P_B)(I_B + G_B) = I_B$ . If B is finite, the matrix  $I_B - P_B$  is invertible.

Now that we can compute  $G_B$ , we can also compute  $H_B$  using the result above. All that remains is for us to compute the hitting probability H(x, y) when x is transient and y is recurrent. The first thing to notice is that the hitting probability is a class property.

Suppose that x is transient and that A is a recurrent class. Then H(x, y) = H(x, A) for  $y \in A$ .

That is, starting in the transient state  $x \in S$ , the hitting probability to y is constant for  $y \in A$ , and is just the hitting probability to the class A. As before, let B denote the set of transient states and suppose that A is a recurrent equivalence class. Let  $h_A$  denote the

function on *B* that gives the hitting probability to class *A*, and let  $p_A$  denote the function on *B* that gives the probability of entering *A* on the first step:

$$h_A(x) = H(x, A), \ p_A(x) = P(x, A), \quad x \in B$$
 (16.4.21)

 $h_A = p_A + G_B p_A$  .

Proof

First note that  $\mathbb{P}(\tau_A = n \mid X_0 = x) = (P_B^{n-1}p_A)(x)$  for  $n \in \mathbb{N}_+$ . The result then follows by summing over n.

This result is adequate if we have already computed  $G_B$  (using the result in above, for example). However, we might just want to compute  $h_A$  directly.

 $h_A$  satisfies the equation  $h_A = p_A + P_B h_A$  and is the smallest nonnegative solution. If B is finite,  $h_A = (I_B - P_B)^{-1} p_A$ .

Proof

First, conditioning on  $X_1$  gives  $h_A = p_A + P_B h_A$ . Next suppose that h is nonnegative and satisfies  $h = p_A + P_B h$ . Then  $h = p_A + \sum_{k=1}^{n-1} P_B^k p_A + P_B^n h$  for each  $n \in \mathbb{N}_+$ . Hence  $h \ge p_A + \sum_{k=1}^{n-1} P_B^k p_A$ . Letting  $n \to \infty$  gives  $h \ge h_A$ . The representation when B is finite follows from the result above.

State graph

## **Examples and Applications**

#### **Finite Chains**

Consider a Markov chain with state space  $S = \{a, b, c, d\}$  and transition matrix P given below:

## 16.5: Periodicity of Discrete-Time Chains

A state in a discrete-time Markov chain is periodic if the chain can return to the state only at multiples of some integer larger than 1. Periodic behavior complicates the study of the limiting behavior of the chain. As we will see in this section, we can eliminate the periodic behavior by considering the *d*-step chain, where  $d \in \mathbb{N}_+$  is the period, but only at the expense of introducing additional equivalence classes. Thus, in a sense, we can trade one form of complexity for another.

## Basic Theory

### **Definitions and Basic Results**

As usual, our starting point is a (time homogeneous) discrete-time Markov chain  $X = (X_0, X_1, X_2, ...)$  with (countable) state space *S* and transition probability matrix *P*.

The *period* of state  $x \in S$  is

 $d(x) = \gcd\{n \in \mathbb{N}_+ : P^n(x, x) > 0\}$ (16.5.1)

State *x* is *aperiodic* if d(x) = 1 and *periodic* if d(x) > 1.

Thus, starting in x, the chain can return to x only at multiples of the period d, and d is the largest such integer. Perhaps the most important result is that period, like recurrence and transience, is a *class property*, shared by all states in an equivalence class under the *to and from* relation.

If 
$$x \leftrightarrow y$$
 then  $d(x) = d(y)$ .

Proof

Suppose that  $x \leftrightarrow y$ . The result is trivial if x = y, so let's assume that  $x \neq y$ . Recall that there exist  $j, k \in \mathbb{N}_+$  such that  $P^j(x, y) > 0$  and  $P^k(y, x) > 0$ . But then  $P^{j+k}(x, x) \ge P^j(x, y)P^k(y, x) > 0$  and hence  $d(x) \mid (j+k)$ . Suppose now that n is a positive integer with  $P^n(y, y) > 0$ . Then  $P^{j+k+n}(x, x) \ge P^j(x, y)P^n(y, y)P^k(y, x) > 0$  and hence  $d(x) \mid (j+k+n)$ . It follows that  $d(x) \mid n$ . From the definition of period,  $d(y) \mid d(x)$ . Reversing the roles of x and y we also have  $d(x) \mid d(y)$ . Hence d(x) = d(y).

Thus, the definitions of *period*, *periodic*, and *aperiodic* apply to equivalence classes as well as individual states. When the chain is irreducible, we can apply these terms to the entire chain.

Suppose that  $x \in S$ . If P(x, x) > 0 then x (and hence the equivalence class of x) is aperiodic.

#### Proof

By assumption,  $1 \in \{n \in \mathbb{N}_+ : P^n(x,x) > 0\}$  and hence the greatest common divisor of this set is 1.

The converse is not true, of course. A simple counterexample is given below.

#### The Cyclic Classes

Suppose now that  $\mathbf{X} = (X_0, X_1, X_2, ...)$  is irreducible and is periodic with period d. There is no real loss in generality in assuming that the chain is irreducible, for if this were not the case, we could simply restrict our attention to one of the irreducible equivalence classes. Our exposition will be easier and cleaner if we recall the congruence equivalence relation modulo d on  $\mathbb{Z}$ , which in turn is based on the divison partial order. For  $n, m \in \mathbb{Z}, n \equiv_d m$  if and only if  $d \mid (n-m)$ , equivalently n-m is an integer multiple of d, equivalently m and n have the same remainder after division by d. The basic fact that we will need is that  $\equiv_d$  is preserved under sums and differences. That is, if  $m, n, p, q \in \mathbb{Z}$  and if  $m \equiv_d n$  and  $p \equiv_d q$ , then  $m + p \equiv_d n + q$  and  $m - p \equiv_d n - q$ .

Now, we fix a reference state  $u \in S$ , and for  $k \in \{0, 1, \dots, d-1\}$ , define

$$A_k = \{x \in S : P^{nd+k}(u, x) > 0 \text{ for some } n \in \mathbb{N}\}$$

$$(16.5.2)$$

That is,  $x \in A_k$  if and only if there exists  $m \in \mathbb{N}$  with  $m \equiv_d k$  and  $P^m(u, x) > 0$ .

#### Suppose that $x, y \in S$ .

- 1. If  $x \in A_j$  and  $y \in A_k$  for  $j, k \in \{0, 1, \dots, d-1\}$  then  $P^n(x, y) > 0$  for some  $n \equiv_d k j$
- 2. Conversely, if  $P^n(x,y)>0$  for some  $n\in\mathbb{N}$ , then there exists  $j,\,k\in\{0,1,\ldots d-1\}$  such that  $x\in A_j,\,y\in A_k$  and
- $n\equiv_d k-j$  .
- 3. The sets  $(A_0, A_1, \ldots, A_{k-1})$  partition *S*.

Proof

Suppose first that  $x \in A_k$ . By definition, u leads to x in m steps for some  $m \equiv_d k$ . Since the chain is irreducible, x leads back to u, say in p steps. It follows that u leads back to u in m + p steps. But because u has period d, we must have  $m + p \equiv_d 0$  and hence  $p \equiv_d -k$ .

Next suppose that  $x \in A_j$  and  $y \in A_k$ . We know that u leads to x in m steps for some  $m \equiv_d j$ , and we now know that y leads to u in p steps for some  $p \equiv_d -k$ . Since the chain is irreducible, x leads to y, say in n steps. It follows that u leads back to u in m + n + p steps. Again, since u has period d,  $m + n + p \equiv_d 0$  and it follows that  $n \equiv_d k - j$ 

Next, note that since the chain is irreducible and since  $\{0, 1, \ldots, d-1\}$  is the set of all remainders modulo d, we must have  $\bigcup_{i=0}^{d-1} A_i = S$ . Suppose that  $x, y \in S$  and  $P^n(x, y) > 0$  for some  $n \in \mathbb{N}$ . Then  $x \in A_j$  and  $y \in A_k$  for some  $j, k \in \{0, 1, \ldots\}$ . By the same argument as the last paragraph, we must have  $n \equiv_d k - j$ .

All that remains is to show that the sets are disjoint, and that amounts to the same old argument yet again. Suppose that  $x \in A_j \cap A_k$  for some  $j, k \in \{0, 1, \dots, d-1\}$ . Then u leads to x in m steps for some  $m \equiv_d j$  and x leads to u in n steps for some  $n \equiv_d -k$ . Hence u leads back to u in m+n steps. Since the chain has period d we have  $m+n \equiv_d 0$  and therefore  $j-k \equiv_d 0$ . Since  $j, k \in \{0, 1, \dots, d-1\}$  it follows that j = k.

 $(A_0, A_1, \ldots, A_{d-1})$  are the equivalence classes for the *d*-step to and from relation  $\underset{d}{\leftrightarrow}$  that governs the *d*-step chain  $(X_0, X_d, X_{2d}, \ldots)$  that has transition matrix  $P^d$ .

The sets  $(A_0, A_1, \ldots, A_{d-1})$  are known as the *cyclic classes*. The basic structure of the chain is shown in the state diagram below:

Figure 16.5.1: The cyclic classes of a chain with period d

## **Examples and Special Cases**

#### **Finite Chains**

Consider the Markov chain with state space  $S = \{a, b, c\}$  and transition matrix *P* given below:

$$P = \begin{bmatrix} 0 & \frac{1}{3} & \frac{2}{3} \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{bmatrix}$$
(16.5.3)

1. Sketch the state graph and show that the chain is irreducible.

2. Show that the chain is aperiodic.

3. Note that P(x, x) = 0 for all  $x \in S$ .

Answer

- 1. The state graph has edge set  $E = \{(a, b), (a, c), (b, c), (b, a)\}$ .
- 2. Note that  $P^2(a, a) > 0$  and  $P^3(a, a) > 0$ . Hence d(a) = 1 since 2 and 3 are relatively prime. Since the chain is irreducible, it is aperiodic.

Consider the Markov chain with state space  $S = \{1, 2, 3, 4, 5, 6, 7\}$  and transition matrix P given below:

	0	0	$\frac{1}{2}$	$\frac{1}{4}$	$\frac{1}{4}$	0	0
	0	0	$\frac{1}{3}$	0	$\frac{2}{3}$	0	0
	0	0	0	0	0	$\frac{1}{3}$	$\frac{2}{3}$
P =	0	0	0	0	0	$\frac{1}{2}$	$\frac{1}{2}$
	0	0	0	0	0	$\frac{3}{4}$	$\frac{1}{4}$
	$\frac{1}{2}$	$\frac{1}{2}$	0	0	0	0	0
	$\frac{1}{4}$	$\frac{3}{4}$	0	0	0	0	0

1. Sketch the state graph and show that the chain is irreducible.

- 2. Find the period d.
- 3. Find  $P^d$ .

4. Identify the cyclic classes.

Answer

1.

```
2. Period 3

## 16.6: Stationary and Limiting Distributions of Discrete-Time Chains

In this section, we study some of the deepest and most interesting parts of the theory of discrete-time Markov chains, involving two different but complementary ideas: stationary distributions and limiting distributions. The theory of renewal processes plays a critical role.

## **Basic Theory**

As usual, our starting point is a (time homogeneous) discrete-time Markov chain  $\mathbf{X} = (X_0, X_1, X_2, ...)$  with (countable) state space S and transition probability matrix P. In the background, of course, is a probability space  $(\Omega, \mathscr{F}, \mathbb{P})$  so that  $\Omega$  is the sample space,  $\mathscr{F}$  the  $\sigma$ -algebra of events, and  $\mathbb{P}$  the probability measure on  $(\Omega, \mathscr{F})$ . For  $n \in \mathbb{N}$ , let  $\mathscr{F}_n = \sigma\{X_0, X_1, ..., X_n\}$ , the  $\sigma$ algebra of events determined by the chain up to time n, so that  $\mathfrak{F} = \{\mathscr{F}_0, \mathscr{F}_1, ...\}$  is the natural filtration associated with  $\mathbf{X}$ .

#### The Embedded Renewal Process

Let  $y \in S$  and  $n \in \mathbb{N}_+$ . We will denote the number of visits to y during the first n positive time units by

$$N_{y,n} = \sum_{i=1}^{n} \mathbf{1}(X_i = y)$$
(16.6.1)

Note that  $N_{y,n} o N_y$  as  $n o \infty$  , where

$$N_y = \sum_{i=1}^{\infty} \mathbf{1}(X_i = y)$$
(16.6.2)

is the total number of visits to y at positive times, one of the important random variables that we studied in the section on transience and recurrence. For  $n \in \mathbb{N}_+$ , we denote the time of the *n*th visit to y by

$$\tau_{y,n} = \min\{k \in \mathbb{N}_+ : N_{y,k} = n\}$$
(16.6.3)

where as usual, we define  $\min(\emptyset) = \infty$ . Note that  $\tau_{y,1}$  is the time of the first visit to y, which we denoted simply by  $\tau_y$  in the section on transience and recurrence. The times of the visits to y are stopping times for X. That is,  $\{\tau_{y,n} = k\} \in \mathscr{F}_k$  for  $n \in \mathbb{N}_+$  and  $k \in \mathbb{N}$ . Recall also the definition of the hitting probability to state y starting in state x:

$$H(x,y)=\mathbb{P}\left( au_{y}<\infty\mid X_{0}=x
ight),\quad (x,y)\in S^{2}$$
 $(16.6.4)$ 

Suppose that  $x, y \in S$ , and that y is recurrent and  $X_0 = x$ .

1. If x = y, then the successive visits to y form a renewal process.

2. If  $x \neq y$  but  $x \rightarrow y$ , then the successive visits to y form a delayed renewal process.

Let  $\tau_{y,0} = 0$  for convenience.

- 1. Given  $X_0 = y$ , the sequence  $(\tau_{y,1}, \tau_{y,2}, ...)$  is the sequence of arrival times of a renewal process. Every time the chain reaches state y, the process starts over, independently of the past, by the Markov property. Thus the interarrival times  $\tau_{y,n+1} \tau_{y,n}$  for  $n \in \mathbb{N}$  are conditionally independent, and are identically distributed, given  $X_0 = y$ .
- 2. If  $x \neq y$  but  $x \to y$ , then given  $X_0 = x$ , the sequence  $(\tau_{y,1}, \tau_{y,2}, \ldots)$  is the sequence of arrival times of a delayed renewal process. By the same argument as in (a), the interarrival times  $\tau_{y,n+1} \tau_{y,n}$  for  $n \in \mathbb{N}$  are conditionally independent, given  $X_0 = x$ , and all but  $\tau_{y,1}$  have the same distribution.

As noted in the proof,  $(\tau_{y,1}, \tau_{y,2}, ...)$  is the sequence of arrival times and  $(N_{y,1}, N_{y,2}, ...)$  is the associated sequence of counting variables for the embedded renewal process associated with the recurrent state y. The corresponding renewal function, given  $X_0 = x$ , is the function  $n \mapsto G_n(x, y)$  where

$$G_n(x,y) = \mathbb{E}\left(N_{y,n} \mid X_0 = x
ight) = \sum_{k=1}^n P^k(x,y), \quad n \in \mathbb{N}$$
 (16.6.5)

Thus  $G_n(x, y)$  is the expected number of visits to y in the first n positive time units, starting in state x. Note that  $G_n(x, y) \rightarrow G(x, y)$  as  $n \rightarrow \infty$  where G is the potential matrix that we studied previously. This matrix gives the expected total number visits to state  $y \in S$ , at positive times, starting in state  $x \in S$ :

$$G(x,y) = \mathbb{E}\left(N_y \mid X_0 = x\right) = \sum_{k=1}^{\infty} P^k(x,y)$$
 (16.6.6)

## Limiting Behavior

The limit theorems of renewal theory can now be used to explore the limiting behavior of the Markov chain. Let  $\mu(y) = \mathbb{E}(\tau_y \mid X_0 = y)$  denote the mean return time to state y, starting in y. In the following results, it may be the case that  $\mu(y) = \infty$ , in which case we interpret  $1/\mu(y)$  as 0.

If  $x, y \in S$  and y is recurrent then

$$\mathbb{P}\left(rac{1}{n}N_{n,y}
ightarrowrac{1}{\mu(y)} ext{ as }n
ightarrow\infty\Big|\,X_0=x
ight)=H(x,y)$$
(16.6.7)

Proof

This result follows from the strong law of large numbers for renewal processes.

Note that  $\frac{1}{n}N_{y,n} = \frac{1}{n}\sum_{k=1}^{n} \mathbf{1}(X_k = y)$  is the average number of visits to y in the first n positive time units.

If  $x, y \in S$  and y is recurrent then

$$rac{1}{n}G_n(x,y) = rac{1}{n}\sum_{k=1}^n P^k(x,y) o rac{H(x,y)}{\mu(y)} ext{ as } n o \infty ext{ (16.6.8)}$$

Proof

This result follows from the elementary renewal theorem for renewal processes.

Note that  $\frac{1}{n}G_n(x,y) = \frac{1}{n}\sum_{k=1}^n P^k(x,y)$  is the expected average number of visits to y during the first n positive time units, starting at x.

If  $x, y \in S$  and y is recurrent and aperiodic then

$$P^n(x,y) 
ightarrow rac{H(x,y)}{\mu(y)} ext{ as } n 
ightarrow \infty$$
 (16.6.9)

Proof

This result follows from the renewal theorem for renewal processes.

Note that H(y, y) = 1 by the very definition of a recurrent state. Thus, when x = y, the law of large numbers above gives convergence with probability 1, and the first and second renewal theory limits above are simply  $1/\mu(y)$ . By contrast, we already know the corresponding limiting behavior when y is transient.

If  $x, y \in S$  and y is transient then

$$egin{aligned} &1. \ \mathbb{P}\left(rac{1}{n}N_{y,n} o 0 ext{ as } n o \infty \mid X_0 = x
ight) = 1 \ &2. \ rac{1}{n}G_n(x,y) = rac{1}{n}\sum_{k=1}^n P^k(x,y) o 0 ext{ as } n o \infty \ &3. \ P^n(x,y) o 0 ext{ as } n o \infty \end{aligned}$$

Proof

1. Note that  $0 \leq \frac{1}{n}N_{y,n} \leq \frac{1}{n}N_y$ . But if y is transient,  $\mathbb{P}(N_y < \infty \mid X_0 = x) = 1$  and hence  $\mathbb{P}(\frac{1}{n}N_y \to 0 \text{ as } n \to \infty \mid X_0 = x) = 1$  so the result follows from the squeeze theorem for limits. 2. Similarly, note that

$$0 \le \frac{1}{n} \sum_{k=1}^{n} P^{k}(x, y) \le \frac{1}{n} \sum_{k=1}^{\infty} P^{k}(x, y)$$
(16.6.10)

If *y* is transient,  $G(x, y) = \sum_{k=1}^{\infty} P^k(x, y) < \infty$  and hence  $\frac{1}{n}G(x, y) \to 0$  as  $n \to \infty$ . Again the result follows from the squeeze theorem for limits.

3. Once more, if *y* is transient,  $G(x, y) = \sum_{k=1}^{\infty} P^k(x, y) < \infty$  and therefore  $P^n(x, y) \to 0$  as  $n \to \infty$ .

On the other hand, if y is transient then  $\mathbb{P}(\tau_y = \infty \mid X_0 = y) > 0$  by the very definition of a transience. Thus  $\mu(y) = \infty$ , and so the results in parts (b) and (c) agree with the corresponding results above for a recurrent state. Here is a summary.

For  $x, y \in S$ ,

$$rac{1}{n}G_n(x,y) = rac{1}{n}\sum_{k=1}^n P^k(x,y) o rac{H(x,y)}{\mu(y)} ext{ as } n o \infty ext{ (16.6.11)}$$

If y is transient or if y is recurrent and aperiodic,

$$P^n(x,y) \to rac{H(x,y)}{\mu(y)} ext{ as } n o \infty$$
 (16.6.12)

#### Positive and Null Recurrence

Clearly there is a fundamental dichotomy in terms of the limiting behavior of the chain, depending on whether the mean return time to a given state is finite or infinite. Thus the following definition is natural.

Let  $x \in S$ .

- 1. State *x* is *positive recurrent* if  $\mu(x) < \infty$ .
- 2. If *x* is recurrent but  $\mu(x) = \infty$  then state *x* is *null recurrent*.

Implicit in the definition is the following simple result:

If  $x \in S$  is positive recurrent, then x is recurrent.

Proof

Recall that if  $\mathbb{E}( au_x \mid X_0 = x) < \infty$  then  $\mathbb{P}( au_x < \infty \mid X_0 = x) = 1$  .

On the other hand, it is possible to have  $\mathbb{P}(\tau_x < \infty \mid X_0 = x) = 1$ , so that x is recurrent, and also  $\mathbb{E}(\tau_x \mid X_0 = x) = \infty$ , so that x is null recurrent. Simply put, a random variable can be finite with probability 1, but can have infinite expected value. A classic example is the Pareto distribution with shape parameter  $a \in (0, 1)$ .

Like recurrence/transience, and period, the null/positive recurrence property is a *class property*.

If *x* is positive recurrent and  $x \rightarrow y$  then *y* is positive recurrent.

Proof

Suppose that x is positive recurrent and  $x \to y$ . Recall that y is recurrent and  $y \to x$ . Hence there exist  $i, j \in \mathbb{N}_+$  such that  $P^i(x, y) > 0$  and  $P^j(y, x) > 0$ . Thus for every  $k \in \mathbb{N}_+$ ,  $P^{i+j+k}(y, y) \ge P^j(y, x)P^k(x, x)P^i(x, y)$ . Averaging over k from 1 to n gives

$$\frac{G_n(y,y)}{n} - \frac{G_{i+j}(y,y)}{n} \ge P^j(y,x) \frac{G_n(x,x)}{n} P^i(x,y)$$
(16.6.13)

Letting  $n \to \infty$  and using renwal theory limit above gives

$$rac{1}{\mu(y)} \geq P^{j}(y,x) rac{1}{\mu(x)} P^{i}(x,y) > 0$$
 (16.6.14)

Therefore  $\mu(y) < \infty$  and so *y* is also positive recurrent.

Thus, the terms *positive recurrent* and *null recurrent* can be applied to equivalence classes (under the *to and from* equivalence relation), as well as individual states. When the chain is irreducible, the terms can be applied to the chain as a whole.

Recall that a nonempty set of states A is *closed* if  $x \in A$  and  $x \to y$  implies  $y \in A$ . Here are some simple results for a finite, closed set of states.

If  $A \subseteq S$  is finite and closed, then A contains a positive recurrent state.

Proof

Fix a state  $x \in A$  and note that  $P^k(x, A) = \sum_{y \in A} P^k(x, y) = 1$  for every  $k \in \mathbb{N}_+$  since A is closed. Averaging over k from 1 to n gives

$$\sum_{y \in A} \frac{G_n(x,y)}{n} = 1 \tag{16.6.15}$$

for every  $n \in \mathbb{N}_+$ . Note that the change in the order of summation is justified since both sums are finite. Assume now that all states in A are transient or null recurrent. Letting  $n \to \infty$  in the displayed equation gives the contradiction 0 = 1. Again, the interchange of sum and limit is justified by the fact that A is finite.

If  $A \subseteq S$  is finite and closed, then A contains no null recurrent states.

Proof

Let  $x \in A$ . Note that  $[x] \subseteq A$  since A is closed. Suppose that x is recurrent. Note that [x] is also closed and finite and hence must have a positive recurrent state by the previous result. Hence the equivalence class [x] is positive recurrent and thus so is x.

If  $A \subseteq S$  is finite and irreducible, then A is a positive recurrent equivalence class.

Proof

We already know that A is a recurrent equivalence class, from our study of transience and recurrence. From the previous theorem, A is positive recurrent.

In particular, a Markov chain with a finite state space cannot have null recurrent states; every state must be transient or positive recurrent.

#### Limiting Behavior, Revisited

Returning to the limiting behavior, suppose that the chain X is irreducible, so that either all states are transient, all states are null recurrent, or all states are positive recurrent. From the basic limit theorem above, if the chain is transient or if the chain is recurrent and aperiodic, then

$$P^n(x,y) o rac{1}{\mu(y)} ext{ as } n o \infty ext{ for every } x \in S ext{ (16.6.16)}$$

Note in particular that the limit is independent of the initial state x. Of course in the transient case and in the null recurrent and aperiodic case, the limit is 0. Only in the positive recurrent, aperiodic case is the limit positive, which motivates our next definition.

A Markov chain *X* that is irreducible, positive recurrent, and aperiodic, is said to be *ergodic*.

In the ergodic case, as we will see,  $X_n$  has a limiting distribution as  $n \to \infty$  that is independent of the initial distribution.

The behavior when the chain is periodic with period  $d \in \{2, 3, ...\}$  is a bit more complicated, but we can understand this behavior by considering the *d*-step chain  $\mathbf{X}_d = (X_0, X_d, X_{2d}, ...)$  that has transition matrix  $P^d$ . Essentially, this allows us to trade *periodicity* (one form of complexity) for *reducibility* (another form of complexity). Specifically, recall that the *d*-step chain is aperiodic but has *d* equivalence classes  $(A_0, A_1, ..., A_{d-1})$ ; and these are the *cyclic classes* of original chain  $\mathbf{X}$ .

Figure 16.6.1: The cyclic classes of a chain with period d

The mean return time to state *x* for the *d*-step chain  $X_d$  is  $\mu_d(x) = \mu(x)/d$ .

Proof

Note that every single step for the d-step chain corresponds to d steps for the original chain.

Let 
$$i, j, k \in \{0, 1, \dots, d-1\}$$
,

 $\begin{array}{l} 1. \ P^{nd+k}(x,y) \to d/\mu(y) \text{ as } n \to \infty \ \text{ if } x \in A_i \ \text{and } y \in A_j \ \text{and } j = (i+k) \mod d \ . \\ 2. \ P^{nd+k}(x,y) \to 0 \ \text{as } n \to \infty \ \text{ in all other cases.} \end{array}$ 

Proof

These results follow from the previous theorem and the cyclic behavior of the chain.

If  $y \in S$  is null recurrent or transient then regardless of the period of y,  $P^n(x, y) \to 0$  as  $n \to \infty$  for every  $x \in S$ .

#### **Invariant Distributions**

Our next goal is to see how the limiting behavior is related to invariant distributions. Suppose that f is a probability density function on the state space S. Recall that f is *invariant* for P (and for the chain X) if fP = f. It follows immediately that  $fP^n = f$  for every  $n \in \mathbb{N}$ . Thus, if  $X_0$  has probability density function f then so does  $X_n$  for each  $n \in \mathbb{N}$ , and hence X is a sequence of identically distributed random variables. A bit more generally, suppose that  $g:S o [0,\infty)$  is invariant for P, and let  $C = \sum_{x \in S} g(x)$ . If  $0 < C < \infty$  then f defined by f(x) = g(x)/C for  $x \in S$  is an invariant probability density function.

Suppose that  $g:S o [0,\infty)$  is invariant for P and satisfies  $\sum_{x\in S}g(x)<\infty$  . Then

$$g(y) = rac{1}{\mu(y)} \sum_{x \in S} g(x) H(x,y), \quad y \in S$$
 (16.6.17)

Proof

Recall again that  $gP^k = g$  for every  $k \in \mathbb{N}$  since g is invariant for P. Averaging over k from 1 to n gives  $gG_n/n = g$  for each  $n \in \mathbb{N}_+$  . Explicitly,

$$\sum_{x\in S} g(x) rac{G_n(x,y)}{n} = g(y), \quad y\in S$$
 (16.6.18)

Letting  $n \to \infty$  and using the limit theorem above gives the result. The dominated convergence theorem justifies interchanging the limit with the sum, since the terms are positive,  $\frac{1}{n}G_n(x,y) \leq 1$ , and  $\sum_{x \in S} g(x) < \infty$ .

Note that if y is transient or null recurrent, then g(y) = 0. Thus, a invariant function with finite sum, and in particular an invariant probability density function must be concentrated on the positive recurrent states.

Suppose now that the chain X is irreducible. If X is transient or null recurrent, then from the previous result, the only nonnegative functions that are invariant for P are functions that satisfy  $\sum_{x\in S}g(x)=\infty$  and the function that is identically 0:  $g=\mathbf{0}$  . In particular, the chain does not have an invariant distribution. On the other hand, if the chain is positive recurrent, then H(x,y) = 1

for all  $x, y \in S$ . Thus, from the previous result, the only possible invariant probability density function is the function f given by  $f(x) = 1/\mu(x)$  for  $x \in S$ . Any other nonnegative function g that is invariant for P and has finite sum, is a multiple of f (and indeed the multiple is sum of the values). Our next goal is to show that f really is an invariant probability density function.

If X is an irreducible, positive recurrent chain then the function f given by  $f(x) = 1/\mu(x)$  for  $x \in S$  is an invariant probability density function for X.

Proof

Let  $f(x) = 1/\mu(x)$  for  $x \in S$ , and let A be a finite subset of S. Then  $\sum_{y \in A} \frac{1}{n}G_n(x,y) \leq 1$  for every  $x \in S$ . Letting  $n \to \infty$  using the basic limit above gives  $\sum_{y \in A} f(y) \leq 1$ . The interchange of limit and sum is justified since A is finite. Since this is true for every finite  $A \subseteq S$ , it follows that  $C \leq 1$  where  $C = \sum_{y \in S} f(y)$ . Note also that C > 0 since the chain is positive recurrent. Next note that

$$\sum_{y \in A} \frac{1}{n} G_n(x, y) P(y, z) \le \frac{1}{n} G_{n+1}(x, z)$$
(16.6.19)

for every  $x, z \in S$ . Letting  $n \to \infty$  gives  $\sum_{y \in A} f(y)P(y, z) \le f(z)$  for every  $z \in S$ . It then follows that  $\sum_{y \in S} f(y)P(y, z) \le f(z)$  for every  $z \in S$ . Suppose that strict inequality holds for some for some  $z \in S$ . Then

$$\sum_{z \in S} \sum_{y \in S} f(y) P(y, z) < \sum_{z \in S} f(z)$$
(16.6.20)

Interchanging the order of summation on the left in the displayed inequality yields the contradiction C < C. Thus f is invariant for P. Hence f/C is an invariant probability density function. By the uniqueness result noted earlier, it follows that f/C = f so that in fact C = 1.

In summary, an irreducible, positive recurrent Markov chain X has a unique invariant probability density function f given by  $f(x) = 1/\mu(x)$  for  $x \in S$ . We also now have a *test* for positive recurrence. An irreducible Markov chain X is positive recurrent if and only if there exists a positive function g on S that is invariant for P and satisfies  $\sum_{x \in S} g(x) < \infty$  (and then, of course, normalizing g would give f).

Consider now a general Markov chain X on S. If X has no positive recurrent states, then as noted earlier, there are no invariant distributions. Thus, suppose that X has a collection of positive recurrent equivalence classes  $(A_i : i \in I)$  where I is a nonempty, countable index set. The chain restricted to  $A_i$  is irreducible and positive recurrent for each  $i \in I$ , and hence has a unique invariant probability density function  $f_i$  on  $A_i$  given by

$$f_i(x) = rac{1}{\mu(x)}, \quad x \in A_i$$
 (16.6.21)

We extend  $f_i$  to S by defining  $f_i(x) = 0$  for  $x \notin A_i$ , so that  $f_i$  is a probability density function on S. All invariant probability density functions for X are mixtures of these functions:

f is an invariant probability density function for X if and only if f has the form

$$f(x) = \sum_{i \in I} p_i f_i(x), \quad x \in S$$
 (16.6.22)

where  $(p_i : i \in I)$  is a probability density function on the index set I. That is,  $f(x) = p_i f_i(x)$  for  $i \in I$  and  $x \in A_i$ , and f(x) = 0 otherwise.

Proof

Let  $A = \bigcup_{i \in I} A_i$ , the set of positive recurrent states. Suppose that f has the form given in the theorem. Since f(x) = 0 for  $x \notin A$  we have

$$(fP)(y) = \sum_{x \in S} f(x)P(x,y) = \sum_{i \in I} \sum_{x \in A_i} p_i f_i(x)P(x,y)$$
 (16.6.23)

Suppose that  $y\in A_j$  for some  $j\in I$  . Since P(x,y)=0 if  $x\in A_i$  and i
eq j , the last sum becomes

$$(fP)(y) = p_j \sum_{x \in A_j} f_j(x) P(x, y) = p_j f_j(y) = f(y)$$
 (16.6.24)

because  $f_j$  is invariant for the P restricted to  $A_j$ . If  $y \notin A$  then P(x, y) = 0 for  $x \in A$  so the sum above becomes (fP)(y) = 0 = f(y). Hence f is invariant. Moreover,

$$\sum_{x \in S} f(x) = \sum_{i \in I} \sum_{x \in A_i} f(x) = \sum_{i \in I} p_i \sum_{x \in A_i} f_i(x) = \sum_{i \in I} p_i = 1$$
(16.6.25)

so *f* is a PDF on *S*. Conversely, suppose that *f* is an invariant PDF for *X*. We know that *f* is concentrated on the positive recurrent states, so f(x) = 0 for  $x \notin A$ . For  $i \in I$  and  $y \in A_i$ 

$$\sum_{x \in A_i} f(x) P(x, y) = \sum_{x \in S} f(x) P(x, y) = f(y)$$
(16.6.26)

since f is invariant for P and since, as noted before, f(x)P(x, y) = 0 if  $x \notin A_i$ . It follows that f restricted to  $A_i$  is invariant for the chain restricted to  $A_i$  for each  $i \in I$ . Let  $p_i = \sum_{x \in A_i} f(x)$ , the normalizing constant for f restricted to  $A_i$ . By uniqueness, the restriction of  $f/p_i$  to  $A_i$  must be  $f_i$ , so f has the form given in the theorem.

#### **Invariant Measures**

Suppose that **X** is irreducible. In this section we are interested in general functions  $g: S \to [0, \infty)$  that are invariant for **X**, so that gP = g. A function  $g: S \to [0, \infty)$  defines a positive measure  $\nu$  on *S* by the simple rule

$$u(A) = \sum_{x \in A} g(x), \quad A \subseteq S$$

$$(16.6.27)$$

so in this sense, we are interested in invariant positive measures for X that may not be probability measures. Technically, g is the density function of  $\nu$  with respect to counting measure # on S.

From our work above, We know the situation if X is positive recurrent. In this case, there exists a unique invariant probability density function f that is positive on S, and every other nonnegative invariant function g is a nonnegative multiples of f. In particular, either  $g = \mathbf{0}$ , the zero function on S, or g is positive on S and satisfies  $\sum_{x \in S} g(x) < \infty$ .

We can generalize to chains that are simply recurrent, either null or positive. We will show that there exists a positive invariant function that is unique, up to multiplication by positive constants. To set up the notation, recall that  $\tau_x = \min\{k \in \mathbb{N}_+ : X_k = x\}$  is the first positive time that the chain is in state  $x \in S$ . In particular, if the chain starts in x then  $\tau_x$  is the time of the first return to x. For  $x \in S$  we define the function  $\gamma_x$  by

$$\gamma_x(y) = \mathbb{E}\left(\sum_{n=0}^{ au_x-1} \mathbf{1}(X_n=y) \ \Big| \ X_0 = x
ight), \quad y \in S$$
 $(16.6.28)$ 

so that  $\gamma_x(y)$  is the expected number of visits to y before the first return to x, starting in x. Here is the existence result.

Suppose that  $\boldsymbol{X}$  is recurrent. For  $x \in S$ ,

1.  $\gamma_x(x)=1$ 2.  $\gamma_x$  is invariant for  $oldsymbol{X}$ 3.  $\gamma_x(y)\in(0,\infty)$  for  $y\in S.$ 

Proof

1. By definition, given  $X_0 = x$ , we have  $X_0 = x$  but  $X_n \neq x$  for  $n \in \{1, \ldots, \tau_x - 1\}$ . Hence  $\gamma_x(x) = 1$ . 2. Since the chain is recurrent, with probability 1 we have  $\tau_x < \infty$  and  $X_{\tau_x} = x$ . Hence for  $y \in S$ ,

$$\gamma_x(y) = \mathbb{E}\left(\sum_{n=0}^{\tau_x - 1} \mathbf{1}(X_n = y) \ \Big| \ X_0 = x\right) = \mathbb{E}\left(\sum_{n=1}^{\tau_x} \mathbf{1}(X_n = y) \ \Big| \ X_0 = x\right)$$
(16.6.29)

(Note that if x = y then with probability 1, the n = 0 term in the first sum and the  $n = \tau_x$  term in the second sum are 1 and the remaining terms are 0. If  $x \neq y$ , the n = 0 term in the first sum and the  $n = \tau_x$  term in the second sum are 0 with probability 1, so again the two sums are the same.) Hence

$$\gamma_x(y) = \mathbb{E}\left(\sum_{n=1}^{\infty} \mathbf{1}(X_n = y, au_x \ge n) \ \Big| \ X_0 = x\right) = \sum_{n=1}^{\infty} \mathbb{P}(X_n = y, au_x \ge n \ | \ X_0 = x)$$
(16.6.30)

Next we partition on the values of  $X_{n-1}$  in the sum to obtain

$$egin{aligned} &\gamma_x(y) \; = \sum_{n=1}^\infty \sum_{z\in S} \mathbb{P}(X_n = y, X_{n-1} = z, au_x \geq n \mid X_0 = x) \ &= \sum_{n=1}^\infty \sum_{z\in S} \mathbb{P}(X_n = y \mid X_{n-1} = z, au_x \geq n, X_0 = x) \mathbb{P}(X_{n-1} = z, au_x \geq n \mid X_0 = x) \end{aligned}$$

But  $\{X_0 = x, \tau_x \ge n\} \in \mathscr{F}_{n-1}$  (that is, the events depend only on  $(X_0, \ldots, X_{n-1})$ ). Hence by the Markov property, the first factor in the last displayed equation is simply  $\mathbb{P}(X_n = y \mid X_{n-1} = z) = P(z, y)$ . Substituting and re-indexing the sum gives

$$egin{aligned} &\gamma_x(y) &= \sum_{n=1}^\infty \sum_{z\in S} P(z,y) \mathbb{P}(X_{n-1}=z, au_x\geq n \mid X_0=x) = \sum_{z\in S} P(z,y) \mathbb{E}\left(\sum_{n=1}^{ au_x} \mathbf{1}(X_{n-1}=z) \mid X_0=x
ight) \ &= \sum_{z\in S} P(z,y) \mathbb{E}\left(\sum_{m=0}^{ au_x-1} \mathbf{1}(X_m=z) \mid X_0=x
ight) = \sum_{z\in S} P(z,y) \gamma_x(z) = \gamma_x P(y) \end{aligned}$$

3. By the invariance in part (b),  $\gamma_x = \gamma_x P^n$  for every  $n \in \mathbb{N}$ . Let  $y \in S$ . Since the chain is irreducible, there exists  $j \in \mathbb{N}$  such that  $P^j(x, y) > 0$ . Hence

$$\gamma_x(y) = \gamma_x P^j(y) \ge \gamma_x(x) P^j(x,y) = P^j(x,y) > 0$$
 (16.6.31)

Similarly, there exists  $k \in \mathbb{N}$  such that  $P^k(y,x) > 0$  . Hence

$$1 = \gamma_x(x) = \gamma_x P^k(x) \ge \gamma_x(y) P^k(y, x)$$
(16.6.32)

and therefore  $\gamma_x(y) \leq 1/P^k(y,x) < \infty$  .

Next is the uniqueness result.

Suppose again that X is recurrent and that  $g: S \to [0, \infty)$  is invariant for X. For fixed  $x \in S$ ,

$$g(y) = g(x)\gamma_x(y), \quad y \in S$$
 (16.6.33)

Proof

Let  $S_x = S - \{x\}$  and let  $y \in S$ . Since g is invariant,

$$g(y) = gP(y) = \sum_{z \in S} g(z)P(z,y) = \sum_{z \in S_x} g(z)P(z,y) + g(x)P(x,y)$$
(16.6.34)

Note that the last term is  $g(x)\mathbb{P}(X_1 = y, \tau_x \ge 1 \mid X_0 = x)$  . Repeating the argument for g(z) in the sum above gives

$$g(y) = \sum_{z \in S_x} \sum_{w \in S_x} g(w) P(w, z) P(z, y) + g(x) \sum_{z \in S_x} P(x, z) P(z, y) + g(x) P(x, y)$$
(16.6.35)

The last two terms are

$$g(x)\left[\mathbb{P}(X_2 = y, \tau_x \ge 2 \mid X_0 = x) + \mathbb{P}(X_1 = y, \tau_x \ge 1 \mid X_0 = x)\right]$$
(16.6.36)

Continuing in this way shows that for each  $n \in \mathbb{N}_+$  ,

$$g(y) \ge g(x) \sum_{k=1}^{n} \mathbb{P}(X_k = y, au_x \ge k \mid X_0 = x)$$
 (16.6.37)

Letting  $n \to \infty$  then shows that  $g(y) \ge g(x)\gamma_x(y)$ . Next, note that the function  $h = g - g(x)\gamma_x$  is invariant, since it is a difference of two invariant functions, and as just shown, is nonnegative. Also,  $h(x) = g(x) - g(x)\gamma_x(x) = 0$ . Let  $y \in S$ . Since the chain is irreducible, there exists  $j \in \mathbb{N}$  such that  $P^j(y, x) > 0$ . Hence

$$0 = h(x) = hP^{j}(x) \ge h(y)P^{j}(y,x) \ge 0$$
(16.6.38)

Since  $P^{j}(y, x) > 0$  it follows that h(y) = 0.

Thus, suppose that X is null recurrent. Then there exists an invariant function g that is positive on S and satisfies  $\sum_{x \in S} g(x) = \infty$ . Every other nonnegative invariant function is a nonnegative multiple of g. In particular, either  $g = \mathbf{0}$ , the zero function on S, or g is positive on S and satisfies  $\sum_{x \in S} g(x) = \infty$ . The section on reliability chains gives an example of the invariant function for a null recurrent chain.

The situation is complicated when X is transient. In this case, there may or may not exist nonnegative invariant functions that are not identically 0. When they do exist, they may not be unique (up to multiplication by nonnegative constants). But we still know that there are no invariant probability density functions, so if g is a nonnegative function that is invariant for X then either g = 0 or  $\sum_{x \in S} g(x) = \infty$ . The section on random walks on graphs provides lots of examples of transient chains with nontrivial invariant functions. In particular, the non-symmetric random walk on  $\mathbb{Z}$  has a two-dimensional space of invariant functions.

## **Examples and Applications**

#### **Finite Chains**

Consider again the general two-state chain on  $S = \{0, 1\}$  with transition probability matrix given below, where  $p \in (0, 1)$  and  $q \in (0, 1)$  are parameters.

$$P = \begin{bmatrix} 1-p & p \\ q & 1-q \end{bmatrix}$$
(16.6.39)

- 1. Find the invariant distribution.
- 2. Find the mean return time to each state.
- 3. Find  $\lim_{n\to\infty} P^n$  without having to go to the trouble of diagonalizing P, as we did in the introduction to discrete-time chains.

Answer

1. 
$$f = \left(\frac{q}{p+q}, \frac{p}{p+q}\right)$$
  
2.  $\mu = \left(\frac{p+q}{q}, \frac{p+q}{p}\right)$   
3.  $P^n \rightarrow \frac{1}{p+q} \begin{bmatrix} q & p \\ q & p \end{bmatrix}$  as  $n \rightarrow \infty$ .

Consider a Markov chain with state space  $S = \{a, b, c, d\}$  and transition matrix P given below:

$$P = \begin{bmatrix} \frac{1}{3} & \frac{2}{3} & 0 & 0\\ 1 & 0 & 0 & 0\\ 0 & 0 & 1 & 0\\ \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} \end{bmatrix}$$
(16.6.40)

- 1. Draw the state diagram.
- 2. Determine the equivalent classes and classify each as transient or positive recurrent.
- 3. Find all invariant probability density functions.
- 4. Find the mean return time to each state.

5. Find  $\lim_{n\to\infty} P^n$ .

Answer

2.  $\{a, b\}$  recurrent;  $\{c\}$  recurrent;  $\{d\}$  transient.

$$\begin{aligned} 3. \ f &= \left(\frac{3}{5}p, \frac{2}{5}p, 1-p, 0\right), \ 0 \leq p \leq 1 \\ 4. \ \mu &= \left(\frac{5}{3}, \frac{5}{2}, 1, \infty\right) \end{aligned}$$

State graph

5. 
$$P^n \rightarrow \begin{bmatrix} \frac{3}{5} & \frac{2}{5} & 0 & 0\\ \frac{3}{5} & \frac{2}{5} & 0 & 0\\ 0 & 0 & 1 & 0\\ \frac{2}{5} & \frac{4}{15} & \frac{1}{3} & 0 \end{bmatrix}$$
 as  $n \rightarrow \infty$ 

Consider a Markov chain with state space  $S = \{1, 2, 3, 4, 5, 6\}$  and transition matrix P given below:

$$P = \begin{bmatrix} 0 & 0 & \frac{1}{2} & 0 & \frac{1}{2} & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ \frac{1}{4} & 0 & \frac{1}{2} & 0 & \frac{1}{4} & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & \frac{1}{3} & 0 & \frac{2}{3} & 0 \\ 0 & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & 0 & \frac{1}{4} \end{bmatrix}$$
(16.6.41)

1. Sketch the state graph.

2. Find the equivalence classes and classify each as transient or positive recurrent.

3. Find all invariant probability density functions.

4. Find the mean return time to each state.

5. Find  $\lim_{n\to\infty} P^n$ .

Answer

1.

State graph

2. 
$$\{1, 3, 5\}$$
 recurrent;  $\{2, 6\}$  transient;  $\{4\}$  recurrent

$$\begin{aligned} 3. \ f &= \left(\frac{\frac{2}{19}p, 0, \frac{8}{19}p, 1-p, \frac{9}{19}p, 0\right), \quad 0 \leq p \leq 1 \\ 4. \ \mu &= \left(\frac{\frac{19}{2}, \infty, \frac{19}{8}, 1, \frac{19}{8}, \infty\right) \\ 5. \ P^n &\to \left[\begin{array}{ccc} \frac{2}{19} & 0 & \frac{8}{19} & 0 & \frac{9}{19} & 0 \\ \frac{1}{19} & 0 & \frac{4}{19} & \frac{1}{2} & \frac{9}{38} & 0 \\ \frac{2}{19} & 0 & \frac{8}{19} & 0 & \frac{9}{19} & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ \frac{2}{19} & 0 & \frac{8}{19} & 0 & \frac{9}{19} & 0 \\ \frac{1}{19} & 0 & \frac{4}{19} & \frac{1}{2} & \frac{9}{38} & 0 \end{array}\right] \text{ as } n \to \infty. \end{aligned}$$

Consider a Markov chain with state space  $S = \{1, 2, 3, 4, 5, 6\}$  and transition matrix P given below:

$$P = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} & 0 & 0 & 0 & 0\\ \frac{1}{4} & \frac{3}{4} & 0 & 0 & 0 & 0\\ \frac{1}{4} & 0 & \frac{1}{2} & \frac{1}{4} & 0 & 0\\ \frac{1}{4} & 0 & \frac{1}{4} & \frac{1}{4} & 0 & \frac{1}{4}\\ 0 & 0 & 0 & 0 & \frac{1}{2} & \frac{1}{2}\\ 0 & 0 & 0 & 0 & \frac{1}{2} & \frac{1}{2} \end{bmatrix}$$
(16.6.42)

1. Sketch the state graph.

2. Find the equivalence classes and classify each as transient or positive recurrent.

3. Find all invariant probability density functions.

4. Find the mean return time to each state.

5. Find  $\lim_{n\to\infty} P^n$ .

Answer

1.								State graph	
2. $\{1, 2\}$ r	ecurre	ent; {	3,4	}tra	nsie	nt; {	$5,6\}$ recurrent.		
3. $f = \left(\frac{1}{3}p, \frac{2}{3}p, 0, 0, \frac{1}{2}(1-p), \frac{1}{2}(1-p)\right),  0 \le p \le 1$									
4. $\mu = (3,$	$\frac{3}{2}, \infty$	$\infty,\infty,$	2, 2	)					
	$\begin{bmatrix} \frac{1}{3} \end{bmatrix}$	$\frac{2}{3}$	0	0	0	0

## 16.7: Time Reversal in Discrete-Time Chains

The Markov property, stated in the form that the past and future are independent given the present, essentially treats the past and future symmetrically. However, there is a lack of symmetry in the fact that in the usual formulation, we have an *initial* time 0, but not a *terminal* time. If we introduce a terminal time, then we can run the process backwards in time. In this section, we are interested in the following questions:

- Is the new process still Markov?
- If so, how does the new transition probability matrix relate to the original one?
- Under what conditions are the forward and backward processes stochastically the same?

Consideration of these questions leads to reversed chains, an important and interesting part of the theory of Markov chains.

## **Basic Theory**

### **Reversed Chains**

Our starting point is a (homogeneous) discrete-time Markov chain  $X = (X_0, X_1, X_2, ...)$  with (countable) state space S and transition probability matrix P. Let m be a positive integer, which we will think of as the *terminal time* or *finite time horizon*. We won't bother to indicate the dependence on m notationally, since ultimately the terminal time will not matter. Define  $\hat{X}_n = X_{m-n}$  for  $n \in \{0, 1, ..., m\}$ . Thus, the process *forward in time* is  $X = (X_0, X_1, ..., X_m)$  while the process *backwards in time* is

$$\hat{\boldsymbol{X}} = (\hat{X}_0, \hat{X}_1, \dots, \hat{X}_m) = (X_m, X_{m-1}, \dots, X_0)$$
(16.7.1)

For  $n\in\{0,1,\ldots,m\}$ , let

$$\hat{\mathscr{F}}_{n} = \sigma\{\hat{X}_{0}, \hat{X}_{1}, \dots, \hat{X}_{n}\} = \sigma\{X_{m-n}, X_{m-n+1}, \dots, X_{m}\}$$
(16.7.2)

denote the  $\sigma$  algebra of the events of the process  $\hat{X}$  up to time n. So of course, an event for  $\hat{X}$  up to time n is an event for X from time m - n forward. Our first result is that the reversed process is still a Markov chain, but not time homogeneous in general.

The process  $\hat{X} = (\hat{X}_0, \hat{X}_1, \dots, \hat{X}_m)$  is a Markov chain, but is not time homogenous in general. The one-step transition matrix at time  $n \in \{0, 1, \dots, m-1\}$  is given by

$$\mathbb{P}(\hat{X}_{n+1} = y \mid \hat{X}_n = x) = \frac{\mathbb{P}(X_{m-n-1} = y)}{\mathbb{P}(X_{m-n} = x)} P(y, x), \quad (x, y) \in S^2$$
(16.7.3)

Proof

Let  $A\in\hat{\mathscr{F}}_n$  and  $x,\,y\in S.$  Then

$$\begin{split} \mathbb{P}(\hat{X}_{n+1} = y \mid \hat{X}_n = x, A) &= \frac{\mathbb{P}(\hat{X}_{n+1} = y, \hat{X}_n = x, A)}{\mathbb{P}(\hat{X}_n = x, A)} = \frac{\mathbb{P}(X_{m-n-1} = y, X_{m-n} = x, A)}{\mathbb{P}(X_{m-n} = x, A)} \\ &= \frac{\mathbb{P}(A \mid X_{m-n-1} = y, X_{m-n} = x) \mathbb{P}(X_{m-n} = x \mid X_{m-n-1} = y) \mathbb{P}(X_{m-n-1} = y)}{\mathbb{P}(A \mid X_{m-n} = x) \mathbb{P}(X_{m-n} = x)} \end{split}$$

But  $A \in \sigma \{X_{m-n}, \ldots, X_m\}$  and so by the Markov property for  $oldsymbol{X}$ ,

$$\mathbb{P}(A \mid X_{m-n-1} = y, X_{m-n} = x) = \mathbb{P}(A \mid X_{m-n} = x)$$
(16.7.4)

By the time homogeneity of  $m{X}, \mathbb{P}(X_{m-n}=x \mid X_{m-n-1}=y) = P(y,x)$  . Substituting and simplifying gives

$$\mathbb{P}(\hat{X}_{n+1} = y \mid \hat{X}_n = x, A) = \frac{\mathbb{P}(X_{m-n-1} = y)}{\mathbb{P}(X_{m-n} = x)} P(y, x)$$
(16.7.5)

However, the backwards chain will be time homogeneous if  $X_0$  has an invariant distribution.

Suppose that X is irreducible and positive recurrent, with (unique) invariant probability density function f. If  $X_0$  has the invariant probability distribution, then  $\hat{X}$  is a time-homogeneous Markov chain with transition matrix  $\hat{P}$  given by

$$\hat{P}(x,y) = rac{f(y)}{f(x)} P(y,x), \quad (x,y) \in S^2$$
(16.7.6)

Proof

This follows from the result above. Recall that if  $X_0$  has PDF f, then  $X_k$  has PDF f for each  $k \in \mathbb{N}$ .

Recall that a discrete-time Markov chain is *ergodic* if it is irreducible, positive recurrent, and aperiodic. For an ergodic chain, the previous result holds in the limit of the terminal time.

Suppose that X is ergodic, with (unique) invariant probability density function f. Regardless of the distribution of  $X_0$ ,

$$\mathbb{P}(\hat{X}_{n+1} = y \mid \hat{X}_n = x) \to \frac{f(y)}{f(x)} P(y, x) \text{ as } m \to \infty$$
(16.7.7)

Proof

This follows from the conditional probability above and our study of the limiting behavior of Markov chains. Since X is ergodic,  $\mathbb{P}(X_k = x) \rightarrow f(x)$  as  $k \rightarrow \infty$  for every  $x \in S$ .

These three results are motivation for the definition that follows. We can generalize by defining the reversal of an irreducible Markov chain, as long as there is a positive, invariant function. Recall that a positive invariant function defines a positive measure on S, but of course not in general a probability distribution.

Suppose that X is an irreducible Markov chain with transition matrix P, and that  $g: S \to (0, \infty)$  is invariant for X. The *reversal* of X with respect to g is the Markov chain  $\hat{X} = (\hat{X}_0, \hat{X}_1, ...)$  with transition probability matrix  $\hat{P}$  defined by

$$\hat{P}(x,y) = rac{g(y)}{g(x)} P(y,x), \quad (x,y) \in S^2$$
(16.7.8)

Proof

We need to show that  $\hat{P}$  is a valid transition probability matrix, so that the definition makes sense. Since *g* is invariant for *X*,

$$\sum_{y \in S} \hat{P}(x, y) = \frac{1}{g(x)} \sum_{y \in S} g(y) P(y, x) = \frac{g(x)}{g(x)} = 1, \quad x \in S$$
(16.7.9)

Recall that if g is a positive invariant function for X then so is cg for every positive constant c. Note that g and cg generate the same reversed chain. So let's consider the cases:

Suppose that  $\boldsymbol{X}$  is an irreducible Markov chain on S.

- 1. If *X* is recurrent, then *X* always has a positive invariant function that is unique up to multiplication by positive constants. Hence the reversal of a recurrent chain *X* always exists and is unique, and so we can refer to the reversal of *X* without reference to the invariant function.
- Even better, if *X* is positive recurrent, then there exists a unique invariant probability density function, and the reversal of *X* can be interpreted as the *time* reversal (with respect to a terminal time) when *X* has the invariant distribution, as in the motivating exercises above.
- 3. If *X* is transient, then there may or may not exist a positive invariant function, and if one does exist, it may not be unique (up to multiplication by positive constants). So a transient chain may have no reversals or more than one.

Nonetheless, the general definition is natural, because most of the important properties of the reversed chain follow from the *balance equation* between the transition matrices P and  $\hat{P}$ , and the invariant function g:

$$g(x)\hat{P}(x,y) = g(y)P(y,x), \quad (x,y) \in S^2$$
 (16.7.10)

We will see this balance equation repeated with other objects related to the Markov chains.

Suppose that X is an irreducible Markov chain with invariant function  $g: S \to (0, \infty)$ , and that  $\hat{X}$  is the reversal of X with respect to g. For  $x, y \in S$ ,

1.  $\hat{P}(x,x)=P(x,x)$ 2.  $\hat{P}(x,y)>0$  if and only if P(y,x)>0

Proof

These results follow immediately from the balance equation  $g(x)\hat{P}(x,y) = g(y)P(y,x)$  for  $(x,y) \in S^2$  .

From part (b) it follows that the state graphs of X and  $\hat{X}$  are reverses of each other. That is, to go from the state graph of one chain to the state graph of the other, simply reverse the direction of each edge. Here is a more complicated (but equivalent) version of the balance equation for chains of states:

Suppose again that X is an irreducible Markov chain with invariant function  $g: S \to (0, \infty)$ , and that  $\hat{X}$  is the reversal of X with respect to g. For every  $n \in \mathbb{N}_+$  and every sequence of states  $(x_1, x_2, \ldots, x_n, x_{n+1}) \in S^{n+1}$ ,

$$g(x_1)\hat{P}(x_1, x_2)\hat{P}(x_2, x_3)\cdots\hat{P}(x_n, x_{n+1}) = g(x_{n+1})P(x_{n+1}, x_n)\cdots P(x_3, x_2)P(x_2, x_1)$$
(16.7.11)

Proof

This follows from repeated applications of the basic equation. When n = 1, we have the balance equation itself:

$$g(x_1)\hat{P}(x_1, x_2) = g(x_2)P(x_2, x_1)$$
(16.7.12)

For n=2 ,

$$g(x_1)\hat{P}(x_1,x_2)\hat{P}(x_2,x_3) = g(x_2)P(x_2,x_1)\hat{P}(x_2,x_3) = g(x_3)P(x_3,x_2)P(x_2,x_1)$$
(16.7.13)

Continuing in this manner (or using induction) gives the general result.

The balance equation holds for the powers of the transition matrix:

Suppose again that X is an irreducible Markov chain with invariant function  $g: S \to (0, \infty)$ , and that  $\hat{X}$  is the reversal of X with respect to g. For every  $(x, y) \in S^2$  and  $n \in \mathbb{N}$ ,

$$g(x)\hat{P}^{n}(x,y) = g(y)P^{n}(y,x)$$
(16.7.14)

Proof

When n = 0, the left and right sides are g(x) if x = y and are 0 otherwise. When n = 1, we have the basic balance equation:  $g(x)\hat{P}(x,y) = g(y)P(y,x)$ . In general, for  $n \in \mathbb{N}_+$ , by the previous result we have

$$g(x){\hat{P}}^n(x,y) = \sum_{\substack{(x_1,\ldots,x_{n-1})\in S^{n-1}}} g(x){\hat{P}}(x,x_1){\hat{P}}(x_1,x_2)\cdots{\hat{P}}(x_{n-1},y) \ = \sum_{\substack{(x_1,\ldots,x_{n-1})\in S^{n-1}}} g(y)P(y,x_{n-1})P(x_{n-1},x_{n-2})\cdots P(x_1,x) = g(y)P^n(y,x)$$

We can now generalize the simple result above.

Suppose again that X is an irreducible Markov chain with invariant function  $g: S \to (0, \infty)$ , and that  $\hat{X}$  is the reversal of X with respect to g. For  $n \in \mathbb{N}$  and  $(x, y) \in S^2$ ,

$$egin{aligned} 1. \ P^n(x,x) &= {\hat{P}}^n(x,x) \ 2. \ {\hat{P}}^n(x,y) > 0 ext{ if and only if } P^n(y,x) > 0 \end{aligned}$$

In terms of the state graphs, part (b) has an obvious meaning: If there exists a path of length n from y to x in the original state graph, then there exists a path of length n from x to y in the reversed state graph. The time reversal definition is symmetric with respect to the two Markov chains.

Suppose again that X is an irreducible Markov chain with invariant function  $g: S \to (0, \infty)$ , and that  $\hat{X}$  is the reversal of X with respect to g. Then

- 1. *g* is also invariant for  $\hat{X}$ .
- 2.  $\hat{X}$  is also irreducible.
- 3. *X* is the reversal of  $\hat{X}$  with respect to *g*.

Proof

1. For  $y \in S$ , using the balance equation,

$$\sum_{x \in S} g(x)\hat{P}(x,y) = \sum_{x \in S} g(y)P(y,x) = g(y)$$
(16.7.15)

- 2. Suppose  $(x, y) \in S^2$ . Since X is irreducible, there exist  $n \in \mathbb{N}$  with  $P^n(y, x) > 0$ . But then from the previous result,  $\hat{P}^n(x, y) > 0$ . Hence  $\hat{X}$  is also irreducible.
- 3. This is clear from the symmetric relationship in the fundamental result.

The balance equation also holds for the potential matrices.

Suppose that X and  $\hat{X}$  are time reversals with respect to the invariant function  $g: S \to (0, \infty)$ . For  $\alpha \in (0, 1]$ , the  $\alpha$  potential matrices are related by

$$g(x)\hat{R}_{lpha}(x,y) = g(y)R_{lpha}(y,x), \quad (x,y)\in S^2$$
(16.7.16)

Proof

This follows easily from the result above and the definition of the potential matrices:

$$egin{aligned} g(x)\hat{R}_lpha(x,y) &= g(x)\sum_{n=0}^\inftylpha^n\hat{P}^n(x,y) = \sum_{n=0}^\inftylpha^ng(x)\hat{P}^n(x,y) \ &= \sum_{n=0}^\inftylpha^ng(y)P^n(y,x) = g(y)\sum_{n=0}^\inftylpha^nP^n(y,x) = g(y)R_lpha(y,x) \end{aligned}$$

Markov chains that are time reversals share many important properties:

Suppose that X and  $\hat{X}$  are time reversals. Then

- 1. **X** and  $\hat{X}$  are of the same type (transient, null recurrent, or positive recurrent).
- 2.  $\boldsymbol{X}$  and  $\hat{\boldsymbol{X}}$  have the same period.
- 3. *X* and  $\hat{X}$  have the same mean return time  $\mu(x)$  for every  $x \in S$ .

Proof

Suppose that X and  $\hat{X}$  are time reversals with respect to the invariant function  $g: S \to (0, \infty)$ .

- 1. The expected number of visits to a state  $x \in S$ , starting in x, is the same for both chains:  $\hat{R}(x, x) = R(x, x)$ . Hence either both chains are transient (if the common potential is finite) or both chains are recurrent (if the common potential is infinite). If both chains are recurrent then the invariant function g is unique up to multiplication by positive constants, and both are null recurrent if  $\sum_{x \in S} g(x) = \infty$  and both are positive recurrent if  $\sum_{x \in S} g(x) < \infty$ .
- 2. This follows since  $P^n(x,x) = \hat{P}^n(x,x)$  for all  $n \in \mathbb{N}$  and  $x \in S$ .
- 3. If both chains are transient or both are null recurrent, then  $\mu(x) = \hat{\mu}(x) = \infty$  for all  $x \in S$ . If both chains are positive recurrent, then for all  $n \in \mathbb{N}$  and  $x \in S$ , we have

$$\frac{1}{n}\sum_{k=1}^{n}P^{k}(x,x) = \frac{1}{n}\sum_{k=1}^{n}\hat{P}^{k}(x,x)$$
(16.7.17)

The left side converges to  $1/\mu(x)$  as  $n o \infty$  while the right side converges to  $1/\hat{\mu}(x)$  as  $n o \infty$  .

The main point of the next result is that we don't need to know a-priori that g is invariant for X, if we can guess g and  $\hat{P}$ .

Suppose again that X is irreducible with transition probability matrix P. If there exists a function  $g: S \to (0, \infty)$  and a transition probability matrix  $\hat{P}$  such that  $g(x)\hat{P}(x,y) = g(y)P(y,x)$  for all  $(x,y) \in S^2$ , then

1. g is invariant for X.

2.  $\hat{P}$  is the transition matrix of the reversal of  $\boldsymbol{X}$  with respect to g.

Proof

1. Since  $\hat{P}$  is a transition probability matrix, we have the same computation we have seen before:

$$gP(x) = \sum_{y \in S} g(y)P(y,x) = \sum_{y \in S} g(x)\hat{P}(x,y) = g(x), \quad x \in S$$
 (16.7.18)

2. This follows from (a) and the definition.

As a corollary, if there exists a probability density function f on S and a transition probability matrix  $\hat{P}$  such that  $f(x)\hat{P}(x,y) = f(y)P(y,x)$  for all  $(x,y) \in S^2$  then in addition to the conclusions above, we know that the chains X and  $\hat{X}$  are positive recurrent.

## **Reversible Chains**

Clearly, an interesting special case occurs when the transition matrix of the reversed chain turns out to be the same as the original transition matrix. A chain of this type could be used to model a physical process that is stochastically the same, forward or backward in time.

Suppose again that  $\mathbf{X} = (X_0, X_1, X_2, ...)$  is an irreducible Markov chain with transition matrix P and invariant function  $g: S \to (0, \infty)$ . If the reversal of  $\mathbf{X}$  with respect to g also has transition matrix P, then  $\mathbf{X}$  is said to be *reversible* with respect to g. That is,  $\mathbf{X}$  is reversible with respect to g if and only if

$$g(x)P(x,y) = g(y)P(y,x), \quad (x,y) \in S^2$$
 (16.7.19)

Clearly if X is reversible with respect to the invariant function  $g: S \to (0, \infty)$  then X is reversible with respect to the invariant function cg for every  $c \in (0, \infty)$ . So again, let's review the cases.

Suppose that  $\boldsymbol{X}$  is an irreducible Markov chain on S.

- 1. If *X* is recurrent, there exists a positive invariant function that is unique up to multiplication by positive constants. So *X* is either reversible or not, and we don't have to reference the invariant function *g*.
- 2. If *X* is positive recurrent then there exists a unique invariant probability density function  $f : S \to (0, 1)$ , and again, either *X* is reversible or not. If *X* is reversible, then *P* is the transition matrix of *X* forward or backward in time, when the chain has the invariant distribution.
- 3. If *X* is transient, there may or may not exist positive invariant functions. If there are two or more positive invariant functions that are not multiplies of one another, *X* might be reversible with respect to one function but not the others.

The non-symmetric simple random walk on  $\mathbb{Z}$  falls into the last case. Using the last result in the previous subsection, we can tell whether X is reversible with respect to g without knowing a-priori that g is invariant.

Suppose again that X is irreducible with transition matrix P. If there exists a function  $g: S \to (0, \infty)$  such that g(x)P(x, y) = g(y)P(y, x) for all  $(x, y) \in S^2$ , then

1. g is invariant for X.

2.  $oldsymbol{X}$  is reversible with respect to g

If we have reason to believe that a Markov chain is reversible (based on modeling considerations, for example), then the condition in the previous theorem can be used to find the invariant functions. This procedure is often easier than using the definition of invariance directly. The next two results are minor generalizations:

Suppose again that X is irreducible and that  $g: S \to (0, \infty)$ . Then g is invariant and X is reversible with respect to g if and only if for every  $n \in \mathbb{N}_+$  and every sequence of states  $(x_1, x_2, \ldots x_n, x_{n+1}) \in S^{n+1}$ ,

$$g(x_1)P(x_1, x_2)P(x_2, x_3)\cdots P(x_n, x_{n+1}) = g(x_{n+1})P(x_{n+1}, x_n), \cdots P(x_3, x_2)P(x_2, x_1)$$
(16.7.20)

Suppose again that X is irreducible and that  $g: S \to (0, \infty)$ . Then g is invariant and X is reversible with respect to g if and only if for every  $(x, y) \in S^2$  and  $n \in \mathbb{N}_+$ ,

$$g(x)P^{n}(x,y) = g(y)P^{n}(y,x)$$
(16.7.21)

Here is the condition for reversibility in terms of the potential matrices.

Suppose again that X is irreducible and that  $g: S \to (0, \infty)$ . Then g is invariant and X is reversible with respect to g if and only if

$$g(x)R_{lpha}(x,y)=g(y)R_{lpha}(y,x), \quad lpha\in(0,1], \ (x,y)\in S^2$$
 (16.7.22)

In the positive recurrent case (the most important case), the following theorem gives a condition for reversibility that does not directly reference the invariant distribution. The condition is known as the *Kolmogorov cycle condition*, and is named for Andrei Kolmogorov

Suppose that X is irreducible and positive recurrent. Then X is reversible if and only if for every sequence of states  $(x_1, x_2, \ldots, x_n)$ ,

$$P(x_1, x_2)P(x_2, x_3)\cdots P(x_{n-1}, x_n)P(x_n, x_1) = P(x_1, x_n)P(x_n, x_{n-1})\cdots P(x_3, x_2)P(x_2, x_1)$$
(16.7.23)

Proof

Suppose that X is reversible. Applying the chain result above to the sequence  $(x_1, x_2, ..., x_n, x_1)$  gives the Kolmogorov cycle condition. Conversely, suppose that the Kolmogorov cycle condition holds, and let f denote the invariant probability density function of X. From the cycle condition we have  $P(x, y)P^k(y, x) = P(y, x)P^k(x, y)$  for every  $(x, y) \in S$  and  $k \in \mathbb{N}_+$ . Averaging over k from 1 to n gives

$$P(x,y)\frac{1}{n}\sum_{k=1}^{n}P^{k}(y,x) = P(y,x)\frac{1}{n}\sum_{k=1}^{n}P^{k}(x,y), \quad (x,y)\in S^{2}, \ n\in\mathbb{N}_{+}$$
(16.7.24)

Letting  $n o \infty$  gives f(x)P(x,y) = f(y)P(y,x) for  $(x,y) \in S^2$  , so  $oldsymbol{X}$  is reversible.

Note that the Kolmogorov cycle condition states that the probability of visiting states  $(x_2, x_3, ..., x_n, x_1)$  in sequence, starting in state  $x_1$  is the same as the probability of visiting states  $(x_n, x_{n-1}, ..., x_2, x_1)$  in sequence, starting in state  $x_1$ . The cycle condition is also known as the *balance equation for cycles*.

Figure 16.7.1: The Kolmogorov cycle condition

## Examples and Applications

#### **Finite Chains**

Recall the general two-state chain X on  $S = \{0, 1\}$  with the transition probability matrix

$$P = \begin{bmatrix} 1-p & p \\ q & 1-q \end{bmatrix}$$
(16.7.25)

where  $p, q \in (0, 1)$  are parameters. The chain X is reversible and the invariant probability density function is  $f = \left(\frac{q}{p+q}, \frac{p}{p+q}\right)$ .

## Proof

All we have to do is note that

$$\begin{bmatrix} q & p \end{bmatrix} \begin{bmatrix} 1-p & p \\ q & 1-q \end{bmatrix} = \begin{bmatrix} q & p \end{bmatrix}$$
(16.7.26)

Suppose that X is a Markov chain on a finite state space S with symmetric transition probability matrix P. Thus P(x, y) = P(y, x) for all  $(x, y) \in S^2$ . The chain X is reversible and that the uniform distribution on S is invariant. Proof

All we have to do is note that  $\mathbf{1}(x)P(x,y) = \mathbf{1}(y)P(y,x)$  where  $\mathbf{1}$  is the constant function 1 on S.

Consider the Markov chain **X** on  $S = \{a, b, c\}$  with transition probability matrix *P* given below:

1

	$\left\lceil \frac{1}{4} \right\rceil$	$\frac{1}{4}$	$\frac{1}{2}$	
<b>&gt;</b> =	$\frac{1}{3}$	$\frac{1}{3}$	$\frac{1}{3}$	(16.7.27)
	$\frac{1}{2}$	$\frac{1}{2}$	0	

1. Draw the state graph of  $\boldsymbol{X}$  and note that the chain is irreducible.

2. Find the invariant probability density function f.

3. Find the mean return time to each state.

4. Find the transition probability matrix  $\hat{P}$  of the time-reversed chain  $\hat{X}$ .

5. Draw the state graph of  $\hat{X}$ .

Answer

1.  
2. 
$$f = \left(\frac{6}{17}, \frac{6}{17}, \frac{5}{17}\right)$$
  
3.  $\mu = \left(\frac{17}{6}, \frac{17}{6}, \frac{17}{5}\right)$   
4.  $\hat{P} = \begin{bmatrix} \frac{1}{4} & \frac{1}{3} & \frac{5}{12} \\ \frac{1}{4} & \frac{1}{3} & \frac{5}{12} \\ \frac{3}{5} & \frac{2}{5} & 0 \end{bmatrix}$   
5.

## 16.8: The Ehrenfest Chains

#### **Basic Theory**

The *Ehrenfest chains*, named for Paul Ehrenfest, are simple, discrete models for the exchange of gas molecules between two containers. However, they can be formulated as simple ball and urn models; the balls correspond to the molecules and the urns to the two containers. Thus, suppose that we have two urns, labeled 0 and 1, that contain a total of *m* balls. The state of the system at time  $n \in \mathbb{N}$  is the number of balls in urn 1, which we will denote by  $X_n$ . Our stochastic process is  $\mathbf{X} = (X_0, X_1, X_2, ...)$  with state space  $S = \{0, 1, ..., m\}$ . Of course, the number of balls in urn 0 at time *n* is  $m - X_n$ .

#### The Models

In the basic Ehrenfest model, at each discrete time unit, independently of the past, a ball is selected at random and moved to the other urn.

Figure 16.8.1: The Ehrenfest model

 $\boldsymbol{X}$  is a discrete-time Markov chain on S with transition probability matrix P given by

$$P(x, x-1) = rac{x}{m}, \ P(x, x+1) = rac{m-x}{m}, \quad x \in S$$
 (16.8.1)

Proof

We will give a construction of the chain from a more basic process. Let  $V_n$  be the ball selected at time  $n \in \mathbb{N}_+$ . Thus  $V = (V_1, V_2, ...)$  is a sequence of independent random variables, each uniformly distributed on  $\{1, 2, ..., m\}$ . Let  $X_0 \in S$  be independent of V. (We can start the process any way that we like.) Now define the state process recursively as follows:

$$X_{n+1} = \begin{cases} X_n - 1, & V_{n+1} \le X_n \\ X_n + 1, & V_{n+1} > X_n \end{cases}, \quad n \in \mathbb{N}$$
(16.8.2)

In the Ehrenfest experiment, select the basic model. For selected values of m and selected values of the initial state, run the chain for 1000 time steps and note the limiting behavior of the proportion of time spent in each state.

Suppose now that we modify the basic Ehrenfest model as follows: at each discrete time, independently of the past, we select a ball at random and a urn at random. We then put the chosen ball in the chosen urn.

 $oldsymbol{X}$  is a discrete-time Markov chain on S with the transition probability matrix Q given by

$$Q(x, x-1) = rac{x}{2m}, \ Q(x, x) = rac{1}{2}, \ Q(x, x+1) = rac{m-x}{2m}, \quad x \in S$$
 (16.8.3)

Proof

Again, we can construct the chain from a more basic process. Let  $X_0$  and V be as in Theorem 1. Let  $U_n$  be the urn selected at time  $n \in \mathbb{N}_+$ . Thus  $U = (U_1, U_2, ...)$  is a sequence of independent random variables, each uniformly distributed on  $\{0, 1\}$  (so that U is a fair, Bernoulli trials sequence). Also, U is independent of V and  $X_0$ . Now define the state process recursively as follows:

$$X_{n+1} = \begin{cases} X_n - 1, & V_{n+1} \le X_n, \ U_{n+1} = 0\\ X_n + 1, & V_{n+1} > X_n, \ U_{n+1} = 1\\ X_n, & \text{otherwise} \end{cases}$$
(16.8.4)

Note that  $Q(x,y) = \frac{1}{2}P(x,y)$  for  $y \in \{x-1, x+1\}$ .

In the Ehrenfest experiment, select the modified model. For selected values of *m* and selected values of the initial state, run the chain for 1000 time steps and note the limiting behavior of the proportion of time spent in each state.

#### Classification

The basic and modified Ehrenfest chains are irreducible and positive recurrent.

#### Proof

The chains are clearly irreducible since every state leads to every other state. It follows that the chains are positive recurrent since the state space S is finite.

The basic Ehrenfest chain is periodic with period 2. The cyclic classes are the set of even states and the set of odd states. The two-step transition matrix is

$$P^2(x,x-2) = rac{x(x-1)}{m^2}, \ P^2(x,x) = rac{x(m-x+1)+(m-x)(x+1)}{m^2}, \ P^2(x,x+2) = rac{(m-x)(m-x-1)}{m^2}, \ \ x \in S$$
 (16.8.5)

Proof

Note that returns to a state can only occur at even times, so the chain has period 2. The form of  $P^2$  follows from the formula for P above.

The modified Ehrenfest chain is aperiodic. Proof

Note that P(x,x) > 0 for each  $x \in S$ .

#### Invariant and Limiting Distributions

For the basic and modified Ehrenfest chains, the invariant distribution is the binomial distribution with trial parameter *m* and success parameter  $\frac{1}{2}$ . So the invariant probability density function *f* is given by

$$f(x) = \binom{m}{x} \left(\frac{1}{2}\right)^m, \quad x \in S$$
(16.8.6)

Proof

For the basic chain we have

$$\begin{aligned} (fP)(y) &= f(y-1)P(y-1,y) + f(y+1)P(y+1,y) \\ &= \binom{m}{y-1} \left(\frac{1}{2}\right)^m \frac{m-y+1}{m} + \binom{m}{y+1} \left(\frac{1}{2}\right)^m \frac{y+1}{m} \\ &= \left(\frac{1}{2}\right)^m \left[\binom{m-1}{y-1} + \binom{m-1}{y}\right] = \left(\frac{1}{2}\right)^m \binom{m}{y} = f(y), \quad y \in S \end{aligned}$$

The last step uses a fundamental identity for binomial coefficients. For the modified chain we can use the result for the basic chain:

$$egin{aligned} (fQ)(y) &= f(y-1)Q(y-1,y) + f(y)Q(y,y) + f(y+1)Q(y+1,y) \ &= rac{1}{2}f(y-1)P(y-1,y) + rac{1}{2}f(y+1)P(y+1,y) + rac{1}{2}f(y) = f(y), \quad y \in S \end{aligned}$$

Thus, the invariant distribution corresponds to placing each ball randomly and independently either in urn 0 or in urn 1.

The mean return time to state  $x \in S$  for the basic or modified Ehrenfest chain is  $\mu(x) = 2^m / {m \choose x}$ .

## Proof

This follows from the general theory and the invariant distribution above.

For the basic Ehrenfest chain, the limiting behavior of the chain is as follows:

1.  $P^{2n}(x, y) \rightarrow {m \choose y} \left(\frac{1}{2}\right)^{m-1}$  as  $n \rightarrow \infty$  if  $x, y \in S$  have the same parity (both even or both odd). The limit is 0 otherwise.

2.  $P^{2n+1}(x,y) \rightarrow {m \choose y} (\frac{1}{2})^{m-1}$  as  $n \rightarrow \infty$  if  $x, y \in S$  have oppositie parity (one even and one odd). The limit is 0 otherwise.

#### Proof

These results follow from the general theory and the invariant distribution above, and the fact that the chain is periodic with period 2, with the odd and even integers in *S* as the cyclic classes.

For the modified Ehrenfest chain,  $Q^n(x,y) o {m \choose y} \left( rac{1}{2} 
ight)^m$  as  $n o \infty$  for  $x, \, y \in S.$ 

Proof

Again, this follows from the general theory and the invariant distribution above, and the fact that the chain is aperiodic.

In the Ehrenfest experiment, the limiting binomial distribution is shown graphically and numerically. For each model and for selected values of m and selected values of the initial state, run the chain for 1000 time steps and note the limiting behavior of the proportion of time spent in each state. How do the choices of m, the initial state, and the model seem to affect the rate of convergence to the limiting distribution?

#### Reversibility

The basic and modified Ehrenfest chains are reversible.

#### Proof

Let  $g(x) = \binom{m}{x}$  for  $x \in S$ . The crucial observations are g(x)P(x,y) = g(y)P(y,x) and g(x)Q(x,y) = g(y)Q(y,x) for all  $x, y \in S$ . For the basic chain, if  $x \in S$  then

$$egin{aligned} g(x)P(x,x-1) &= g(x-1)P(x-1,x) = inom{m-1}{x-1} \ g(x)P(x,x+1) &= g(x+1)P(x+1,x) = inom{m-1}{x} \end{aligned}$$

In all other cases, g(x)P(x,y) = g(y)P(y,x) = 0. The reversibility condition for the modified chain follows trivially from that of the basic chain since  $Q(x,y) = \frac{1}{2}P(x,y)$  for  $y = x \pm 1$  (and of course the reversibility condition is trivially satisfied when x = y). Note that the invariant PDF f is simply g normalized. The reversibility condition gives another (and better) proof that f is invariant.

Run the simulation of the Ehrenfest experiment 10,000 time steps for each model, for selected values of *m*, and with initial state 0. Note that at first, you can see the "arrow of time". After a long period, however, the direction of time is no longer evident.

#### **Computational Exercises**

Consider the basic Ehrenfest chain with m = 5 balls, and suppose that  $X_0$  has the uniform distribution on *S*.

1. Compute the probability density function, mean and variance of  $X_1$ .

2. Compute the probability density function, mean and variance of  $X_2$ .

3. Compute the probability density function, mean and variance of  $X_3$ .

4. Sketch the initial probability density function and the probability density functions in parts (a), (b), and (c) on a common set of axes. Answer

1.  $f_1 = \left(\frac{1}{30}, \frac{7}{30}, \frac{7}{30}, \frac{7}{30}, \frac{7}{30}, \frac{1}{30}\right), \mu_1 = \frac{5}{2}, \sigma_1^2 = \frac{19}{12}$ 2.  $f_2 = \left(\frac{7}{150}, \frac{19}{150}, \frac{49}{150}, \frac{49}{150}, \frac{19}{150}, \frac{7}{150}\right), \mu_2 = \frac{5}{2}, \sigma_2^2 = \frac{79}{60}$ 3.  $f_3 = \left(\frac{19}{750}, \frac{133}{750}, \frac{223}{150}, \frac{223}{150}, \frac{133}{150}, \frac{19}{150}\right), \mu_2 = \frac{5}{2}, \sigma_3^2 = \frac{431}{300}$ 

Consider the modified Ehrenfest chain with m = 5 balls, and suppose that the chain starts in state 2 (with probability 1).

1. Compute the probability density function, mean and standard deviation of  $X_1$ .

2. Compute the probability density function, mean and standard deviation of  $X_2$ .

3. Compute the probability density function, mean and standard deviation of  $X_3$ .

4. Sketch the initial probability density function and the probability density functions in parts (a), (b), and (c) on a common set of axes.

Answer

1.  $f_1=(0,0.2,0.5,0.3,0,0)\mu_1=2.1,\,\sigma_1=0.7$ 

2. 
$$f_2 = (0.02, 0.20, 0.42, 0.30, 0.06, 0)\mu_2 = 2.18, \sigma_2 = 0.887$$

3.  $f_3 = (0.030, 0.194, 0.380, 0.300, 0.090, 0.00 \beta) = 2.244, \sigma_3 = 0.984$

# 16.9: The Bernoulli-Laplace Chain

# **Basic Theory**

#### Introduction

The *Bernoulli-Laplace chain*, named for Jacob Bernoulli and Pierre Simon Laplace, is a simple discrete model for the diffusion of two incompressible gases between two containers. Like the Ehrenfest chain, it can also be formulated as a simple ball and urn model. Thus, suppose that we have two urns, labeled 0 and 1. Urn 0 contains j balls and urn 1 contains k balls, where j,  $k \in \mathbb{N}_+$ . Of the j+k balls, r are red and the remaining j+k-r are green. Thus  $r \in \mathbb{N}_+$  and 0 < r < j+k. At each discrete time, independently of the past, a ball is selected at random from each urn and then the two balls are switched. The balls of different colors correspond to molecules of different types, and the urns are the containers. The incompressible property is reflected in the fact that the number of balls in each urn remains constant over time.

Figure 16.9.1: The Bernoulli-Laplace model

Let  $X_n$  denote the number of red balls in urn 1 at time  $n \in \mathbb{N}$ . Then

1.  $k - X_n$  is the number of green balls in urn 1 at time n.

2.  $r - X_n$  is the number of red balls in urn 0 at time n.

3.  $j - r + X_n$  is the number of green balls in urn 0 at time n.

 $X = (X_0, X_1, X_2, ...)$  is a discrete-time Markov chain with state space  $S = \{\max\{0, r-j\}, ..., \min\{k, r\}\}$  and with transition matrix P given by

$$P(x,x-1) = \frac{(j-r+x)x}{jk}, \ P(x,x) = \frac{(r-x)x + (j-r+x)(k-x)}{jk}, \ P(x,x+1) = \frac{(r-x)(k-x)}{jk}; \quad x \in S \quad (16.9.1)$$

Proof

For the state space, note from the previous result that the number of red balls x in urn 1 must satisfy the inequalities  $x \ge 0$ ,  $x \le k$ ,  $x \le r$ , and  $x \ge r-j$ . The Markov property is clear from the model. For the transition probabilities, note that to go from state x to state x-1 we must select a green ball from urn 0 and a red ball from urn 1. The probabilities of these events are (j-r+x)/j and x/k for x and x-1 in S, and the events are independent. Similarly, to go from state x to state x+1 we must select a red ball from urn 0 and a green ball from urn 1. The probabilities of these events are independent. Similarly, to go from state x to state x+1 we must select a red ball from urn 0 and a green ball from urn 1. The probabilities of these events are independent. Finally, to go from state x back to state x, we must select a red ball from both urns or a green ball from both urns. Of course also, P(x, x) = 1 - P(x, x-1) - P(x, x+1)

This is a fairly complicated model, simply because of the number of parameters. Interesting special cases occur when some of the parameters are the same.

Consider the special case j = k, so that each urn has the same number of balls. The state space is  $S = \{\max\{0, r - k\}, \dots, \min\{k, r\}\}$  and the transition probability matrix is

$$P(x,x-1) = \frac{(k-r+x)x}{k^2}, \ P(x,x) = \frac{(r-x)x + (k-r+x)(k-x)}{k^2}, \ P(x,x+1) = \frac{(r-x)(k-x)}{k^2}; \quad x \in S \quad (16.9.2)$$

Consider the special case r = j, so that the number of red balls is the same as the number of balls in urn 0. The state space is  $S = \{0, ..., \min\{j, k\}\}$  and the transition probability matrix is

$$P(x, x-1) = \frac{x^2}{jk}, \ P(x, x) = \frac{x(j+k-2x)}{jk}, \ P(x, x+1) = \frac{(j-x)(k-x)}{jk}; \quad x \in S$$
(16.9.3)

Consider the special case r = k, so that the number of red balls is the same as the number of balls in urn 1. The state space is  $S = \{\max\{0, k - j\}, \dots, k\}$  and the transition probability matrix is

$$P(x,x-1) = \frac{(j-k+x)x}{jk}, \ P(x,x) = \frac{(k-x)(j-k+2x)}{jk}, \ P(x,x+1) = \frac{(k-x)^2}{jk}; \quad x \in S$$
(16.9.4)

Consider the special case j = k = r, so that each urn has the same number of balls, and this is also the number of red balls. The state space is  $S = \{0, 1, ..., k\}$  and the transition probability matrix is

$$P(x,x-1)=rac{x^2}{k^2}, \ P(x,x)=rac{2x(k-x)}{k^2}, \ P(x,x+1)=rac{(k-x)^2}{k^2}; \quad x\in S$$
 (16.9.5)

Run the simulation of the Bernoulli-Laplace experiment for 10000 steps and for various values of the parameters. Note the limiting behavior of the proportion of time spent in each state.

#### Invariant and Limiting Distributions

The Bernoulli-Laplace chain is irreducible.

#### Proof

Note that P(x, x - 1) > 0 whenever  $x, x - 1 \in S$ , and P(x, x + 1) > 0 whenever  $x, x + 1 \in S$ . Hence every state leads to every other state so the chain is irreducible.

Except in the trivial case j = k = r = 1, the Bernoulli-Laplace chain aperiodic.

#### Proof

Consideration of the state probabilities shows that except when j = k = r = 1, the chain has a state x with P(x, x) > 0, so state x is aperiodic. Since the chain is irreducible by the previous result, all states are aperiodic.

The invariant distribution is the hypergeometric distribution with population parameter j + k, sample parameter k, and type parameter r. The probability density function is

$$f(x) = rac{\binom{r}{k}\binom{j+k-r}{k-x}}{\binom{j+k}{k}}, \quad x \in S$$
 (16.9.6)

Proof

A direct proof that (fP)(x) = f(x) for all  $x \in S$  is straightforward but tedious. A better proof follows from the reversibility condition below.

Thus, the invariant distribution corresponds to selecting a sample of k balls at random and without replacement from the j + k balls and placing them in urn 1. The mean and variance of the invariant distribution are

$$\iota = k \frac{r}{j+k}, \ \sigma^2 = k \frac{r}{j+k} \frac{j+k-r}{j+k} \frac{j}{j+k-1}$$
(16.9.7)

The mean return time to each state  $x \in S$  is

$$\mu(x) = \frac{\binom{j+k}{k}}{\binom{r}{x}\binom{j+k-r}{k-x}}$$
(16.9.8)

Proof

This follows from the general theory and the invariant distribution above.

ŀ

$$P^n(x,y) o f(y) = {r \choose y} {r+k-r \choose k-y} / {j+k \choose k}$$
 as  $n o \infty \,$  for  $(x,y) \in S^2.$ 

Proof

This follows from the general theory and the invariant distribution above.

In the simulation of the Bernoulli-Laplace experiment, vary the parameters and note the shape and location of the limiting hypergeometric distribution. For selected values of the parameters, run the simulation for 10000 steps and and note the limiting behavior of the proportion of time spent in each state.

#### Reversibility

The Bernoulli-Laplace chain is reversible. Proof

Let

$$g(x) = {r \choose x} {j+k-r \choose k-x}, \quad x \in S$$
 (16.9.9)

It suffices to show the reversibility condition g(x)P(x, y) = g(y)P(y, x) for all  $x, y \in S$ . It then follows that X is reversible and that g is invariant for X. For  $x \in S$  and  $y = x - 1 \in S$ , the left and right sides of the reversibility condition reduce to

$$\frac{1}{jk} \frac{r!}{(x-1)!(r-x)!} \frac{(j+k-r)!}{(k-x)!(j-r+x-1)!}$$
(16.9.10)

For  $x \in S$  and  $y = x + 1 \in S$  , the left and right sides of the reversibility condition reduce to

$$\frac{1}{jk}\frac{r!}{x!(r-x-1)!}\frac{(j+k-r)!}{(k-x-1)!(j-r+x)!}$$
(16.9.11)

For all other values of  $x, y \in S$ , the reversibility condition is trivially satisfied. The hypergeometric PDF f above is simply g normalized, so this proves that f is also invariant.

Run the simulation of the Bernoulli-Laplace experiment 10,000 time steps for selected values of the parameters, and with initial state 0. Note that at first, you can see the "arrow of time". After a long period, however, the direction of time is no longer evident.

#### **Computational Exercises**

Consider the Bernoulli-Laplace chain with j = 10, k = 5, and r = 4. Suppose that  $X_0$  has the uniform distribution on S. Explicitly give each of the following:

1. The state space S

2. The transition matrix *P*.

3. The probability density function, mean and variance of  $X_1$ .

4. The probability density function, mean and variance of  $X_2$ .

5. The probability density function, mean and variance of  $X_3$ .

Answer

$$\begin{split} &1.\ S = \{0,1,2,3,4\} \\ &2.\ P = \frac{1}{50} \begin{bmatrix} 30 & 20 & 0 & 0 & 0 \\ 7 & 31 & 12 & 0 & 0 \\ 0 & 16 & 28 & 6 & 0 \\ 0 & 0 & 27 & 21 & 2 \\ 0 & 0 & 0 & 40 & 10 \end{bmatrix} \\ &3.\ f_1 = \frac{1}{250} (37,67,67,67,67,12), \mu_1 = \frac{9}{5}, \sigma_1^2 = \frac{32}{25} \\ &4.\ f_2 = \frac{1}{12\ 500} (1579,3889,4489,2289,254), \mu_2 = \frac{83}{50}, \sigma_2^2 = \frac{2413}{2500} \\ &5.\ f_3 = \frac{1}{625\ 000} (74\ 593,223\ 963,234\ 163,85\ 163,7118), \mu_3 = \frac{781}{500}, \sigma_3^2 = \frac{206\ 427}{250\ 000} \end{split}$$

Consider the Bernoulli-Laplace chain with j = k = 10 and r = 6. Give each of the following explicitly:

1. The state space S

2. The transition matrix  $\boldsymbol{P}$ 

3. The invariant probability density function.

Answer

$$\begin{split} 1. \ S &= \{0, 1, 2, 3, 4, 5, 6\} \\ 2. \ P &= \frac{1}{100} \begin{bmatrix} 40 & 60 & 0 & 0 & 0 & 0 & 0 \\ 5 & 50 & 45 & 0 & 0 & 0 & 0 \\ 0 & 12 & 56 & 32 & 0 & 0 & 0 \\ 0 & 0 & 21 & 58 & 21 & 0 & 0 \\ 0 & 0 & 0 & 32 & 56 & 12 & 0 \\ 0 & 0 & 0 & 0 & 45 & 50 & 5 \\ 0 & 0 & 0 & 0 & 0 & 60 & 40 \end{bmatrix} \\ 3. \ f &= \frac{1}{1292}(7, 84, 315, 480, 315, 84, 7) \end{split}$$

# 16.10: Discrete-Time Reliability Chains

# The Success-Runs Chain

Suppose that we have a sequence of *trials*, each of which results in either *success* or *failure*. Our basic assumption is that if there have been  $x \in \mathbb{N}$  consecutive successes, then the probability of success on the next trial is p(x), independently of the past, where  $p : \mathbb{N} \to (0, 1)$ . Whenever there is a failure, we start over, independently, with a new sequence of trials. Appropriately enough, p is called the *success function*. Let  $X_n$  denote the length of the run of successes after n trials.

 $X = (X_0, X_1, X_2, ...)$  is a discrete-time Markov chain with state space  $\mathbb{N}$  and transition probability matrix P given by

$$P(x, x+1) = p(x), \ P(x, 0) = 1 - p(x); \quad x \in \mathbb{N}$$
 (16.10.1)

The Markov chain  $\boldsymbol{X}$  is called the *success-runs chain*.

Now let T denote the trial number of the first failure, starting with a fresh sequence of trials. Note that in the context of the success-runs chain X,  $T = \tau_0$ , the first return time to state 0, starting in 0. Note that T takes values in  $\mathbb{N}_+ \cup \{\infty\}$ , since presumably, it is possible that no failure occurs. Let  $r(n) = \mathbb{P}(T > n)$  for  $n \in \mathbb{N}$ , the probability of at least n consecutive successes, starting with a fresh set of trials. Let  $f(n) = \mathbb{P}(T = n + 1)$  for  $n \in \mathbb{N}$ , the probability of exactly n consecutive successes, starting with a fresh set of trials.

The functions p, r, and f are related as follows:

1. p(x) = r(x+1)/r(x) for  $x \in \mathbb{N}$ 2.  $r(n) = \prod_{x=0}^{n-1} p(x)$  for  $n \in \mathbb{N}$ 3.  $f(n) = [1-p(n)] \prod_{x=0}^{n-1} p(x)$  for  $n \in \mathbb{N}$ 4.  $r(n) = 1 - \sum_{x=0}^{n-1} f(x)$  for  $n \in \mathbb{N}$ 5. f(n) = r(n) - r(n+1) for  $n \in \mathbb{N}$ 

Thus, the functions p, r, and f give equivalent information. If we know one of the functions, we can construct the other two, and hence any of the functions can be used to define the success-runs chain. The function r is the reliability function associated with T.

The function r is characterized by the following properties:

1. r is positive. 2. r(0) = 13. r is strictly decreasing.

The function f is characterized by the following properties:

1. f is positive. 2.  $\sum_{x=0}^{\infty} f(x) \leq 1$ 

Essentially, f is the probability density function of T-1, except that it may be *defective* in the sense that the sum of its values may be less than 1. The leftover probability, of course, is the probability that  $T = \infty$ . This is the critical consideration in the classification of the success-runs chain, which we will consider shortly.

Verify that each of the following functions has the appropriate properties, and then find the other two functions:

1. *p* is a constant in (0, 1). 2. r(n) = 1/(n+1) for  $n \in \mathbb{N}$ . 3. r(n) = (n+1)/(2n+1) for  $n \in \mathbb{N}$ .

4. p(x)=1/(x+2) for  $x\in\mathbb{N}.$ 

Answer

1. p(x) = p for  $x \in \mathbb{N}$ .  $r(n) = p^n$  for  $n \in \mathbb{N}$ .  $f(n) = (1-p)p^n$  for  $n \in \mathbb{N}$ . 2.  $p(x) = \frac{x+1}{x+2}$  for  $x \in \mathbb{N}$ .  $r(n) = \frac{1}{n+1}$  for  $n \in \mathbb{N}$ .  $f(n) = \frac{1}{n+1} - \frac{1}{n}$  for  $n \in \mathbb{N}$ . 3.  $p(x) = \frac{(x+2)(2x+1)}{(x+1)(2x+3)}$  for  $x \in \mathbb{N}$ .  $r(n) = \frac{n+1}{2n+1}$  for  $n \in \mathbb{N}$ .  $f(n) = \frac{n+1}{2n+1} - \frac{n+2}{2n+3}$  for  $n \in \mathbb{N}$ . 4.  $p(x) = \frac{1}{x+2}$  for  $x \in \mathbb{N}$ .  $r(n) = \frac{1}{(n+1)!}$  for  $n \in \mathbb{N}$ .  $f(n) = \frac{1}{(n+1)!} - \frac{1}{(n+2)!}$  for  $n \in \mathbb{N}$ .

In part (a), note that the trials are Bernoulli trials. We have an app for this case.

The success-runs app is a simulation of the success-runs chain based on Bernoulli trials. Run the simulation 1000 times for various values of p and various initial states, and note the general behavior of the chain.

The success-runs chain is irreducible and aperiodic.

Proof

The chain is irreducible, since 0 leads to every other state, and every state leads back to 0. The chain is aperiodic since P(0,0) > 0.

Recall that *T* has the same distribution as  $\tau_0$ , the first return time to 0 starting at state 0. Thus, the classification of the chain as recurrent or transient depends on  $\alpha = \mathbb{P}(T = \infty)$ . Specifically, the success-runs chain is transient if  $\alpha > 0$  and recurrent if  $\alpha = 0$ . Thus, we see that the chain is recurrent if and only if a failure is sure to occur. We can compute the parameter  $\alpha$  in terms of each of the three functions that define the chain.

In terms of p, r, and f,

$$\alpha = \prod_{x=0}^{\infty} p(x) = \lim_{n \to \infty} r(n) = 1 - \sum_{x=0}^{\infty} f(x)$$
(16.10.2)

Compute  $\alpha$  and determine whether the success-runs chain X is transient or recurrent for each of the examples above.

Answer

1.  $\alpha = 0$ , recurrent. 2.  $\alpha = 0$ , recurrent. 3.  $\alpha = \frac{1}{2}$ , transient. 4.  $\alpha = 0$ , recurrent.

Run the simulation of the success-runs chain 1000 times for various values of p, starting in state 0. Note the return times to state 0.

Let  $\mu = \mathbb{E}(T)$ , the expected trial number of the first failure, starting with a fresh sequence of trials.

 $\begin{array}{l} \mu \text{ is related to } \alpha, f, \text{ and } r \text{ as follows:} \\ 1. \text{ If } \alpha > 0 \text{ then } \mu = \infty \\ 2. \text{ If } \alpha = 0 \text{ then } \mu = 1 + \sum_{n=0}^{\infty} nf(n) \\ 3. \mu = \sum_{n=0}^{\infty} r(n) \end{array}$ Proof  $\begin{array}{l} 1. \text{ If } \alpha = \mathbb{P}(T = \infty) > 0 \quad \text{then } \mu = \mathbb{E}(T) = \infty \\ 2. \text{ If } \alpha = 0, \text{ so that } T \text{ takes values in } \mathbb{N}_+, \text{ then } f \text{ is the PDF of } T - 1, \text{ so } \mu = 1 + \mathbb{E}(T - 1) \\ 3. \text{ This is a basic result from the general theory of expected value: } \mathbb{E}(T) = \sum_{n=0}^{\infty} \mathbb{P}(T > n) \end{array}$ 

The success-runs chain  $\boldsymbol{X}$  is positive recurrent if and only if  $\mu < \infty$ .

#### Proof

Since *T* is the return time to 0, starting at 0, and since the chain is irreducible, it follows from the general theory that the chain is positive recurrent if and only if  $\mu = \mathbb{E}(T) < \infty$ .

If *X* is recurrent, then *r* is invariant for *X*. In the positive recurrent case, when  $\mu < \infty$ , the invariant distribution has probability density function *g* given by

$$g(x)=rac{r(x)}{\mu}, \quad x\in\mathbb{N}$$
 (16.10.3)

Proof

If  $y \in \mathbb{N}_+$  then from the result above,

$$(rP)(y) = \sum_{x=0}^{\infty} r(x)P(x,y) = r(y-1)p(y-1) = r(y)$$
(16.10.4)

For y = 0, using the result above again,

$$(rP)(0) = \sum_{x=0}^{\infty} r(x)P(x,0) = \sum_{x=0}^{\infty} r(x)[1-p(x)] = \sum_{x=0}^{\infty} [r(x) - r(x)p(x)] = \sum_{x=0}^{\infty} [r(x) - r(x+1)] \quad (16.10.5)$$

If the chain is recurrent,  $r(n) \to 0$  as  $n \to \infty$  so the last sum collapses to r(0) = 1. Recall that  $\mu = \sum_{n=0}^{\infty} r(n)$ . Hence if  $\mu < \infty$ , so that the chain is positive recurrent, the function g (which is just r normalized) is the invariant PDF.

When X is recurrent, we know from the general theory that every other nonnegative left invariant function is a nonnegative multiple of r

Determine whether the success-runs chain X is transient, null recurrent, or positive recurrent for each of the examples above. If the chain is positive recurrent, find the invariant probability density function.

Answer

1.  $\mu = \frac{1}{1-p}$ , positive recurrent.  $g(x) = (1-p)p^x$  for  $x \in \mathbb{N}$ . 2.  $\alpha = 0$ ,  $\mu = \infty$ , null recurrent. 3.  $\alpha = \frac{1}{2}$ , transient. 4.  $\mu = e - 1$ , positive recurrent.  $g(x) = \frac{1}{(e-1)(x+1)!}$  for  $x \in \mathbb{N}$ .

From (a), the success-runs chain corresponding to Bernoulli trials with success probability  $p \in (0, 1)$  has the geometric distribution on  $\mathbb{N}$ , with parameter 1 - p, as the invariant distribution.

Run the simulation of the success-runs chain 1000 times for various values of p and various initial states. Compare the empirical distribution to the invariant distribution.

# The Remaining Life Chain

Consider a device whose (discrete) time to failure U takes values in  $\mathbb{N}$ , with probability density function f. We assume that f(n) > 0 for  $n \in \mathbb{N}$ . When the device fails, it is immediately (and independently) replaced by an identical device. For  $n \in \mathbb{N}$ , let  $Y_n$  denote the time to failure of the device that is in service at time n.

$$m{Y}=(Y_0,Y_1,Y_2,\ldots)$$
 is a discrete-time Markov chain with state space  $\mathbb N$  and transition probability matrix  $Q$  given by $Q(0,x)=f(x), \; Q(x+1,x)=1; \quad x\in \mathbb N$  (16.10.6)

The Markov chain Y is called the *remaining life chain* with lifetime probability density function f, and has the state graph below.

Figure 16.10.2: State graph of the remaining life chain

We have an app for the remaining life chain whose lifetime distribution is the geometric distribution on  $\mathbb{N}$ , with parameter  $1-p \in (0,1)$ .

Run the simulation of the remaining-life chain 1000 times for various values of p and various initial states. Note the general behavior of the chain.

If *U* denotes the lifetime of a device, as before, note that T = 1 + U is the return time to 0 for the chain *Y*, starting at 0.

**Y** is irreducible, aperiodic, and recurrent.

Proof

From the assumptions on f, state 0 leads to every other state (including 0), and every positive state leads (deterministically) to 0. Thus the chain is irreducible and aperiodic. By assumption,  $\mathbb{P}(U \in \mathbb{N}) = 1$  so  $\mathbb{P}(T < \infty) = 1$  and hence the chain is recurrent.

Now let  $r(n) = \mathbb{P}(U \ge n) = \mathbb{P}(T > n)$  for  $n \in \mathbb{N}$  and let  $\mu = \mathbb{E}(T) = 1 + \mathbb{E}(U)$ . Note that  $r(n) = \sum_{x=n}^{\infty} f(x)$  and  $\mu = 1 + \sum_{x=0}^{\infty} f(x) = \sum_{n=0}^{\infty} r(n)$ .

The success-runs chain X is positive recurrent if and only if  $\mu < \infty$ , in which case the invariant distribution has probability density function g given by

$$g(x)=rac{r(x)}{\mu},\quad x\in\mathbb{N}$$
 (16.10.7)

Proof

Since the chain is irreducible, it is positive recurrent if and only if  $\mu = E(T) < \infty$ . The function r is invariant for Q: for  $y \in \mathbb{N}$ 

$$egin{aligned} (rQ)(y) &= \sum_{x\in\mathbb{N}} r(x)Q(x,y) = r(0)Q(0,y) + r(y+1)Q(y+1,y) \ &= f(y) + r(y+1) = r(y) \end{aligned}$$

In the positive recurrent case,  $\mu$  is the normalizing constant for r, so g is the invariant PDF.

Suppose that Y is the remaining life chain whose lifetime distribution is the geometric distribution on  $\mathbb{N}$  with parameter  $1-p \in (0, 1)$ . Then this distribution is also the invariant distribution.

Proof

By assumption,  $f(x) = (1-p)p^x$  for  $x \in \mathbb{N}$ , and the mean of this distribution is p/(1-p). Hence  $\mu = 1 + p/(1-p) = 1/(1-p)$ , and  $r(x) = \sum_{y=x}^{\infty} f(y) = p^x$  for  $x \in \mathbb{N}$ . Hence g = f.

Run the simulation of the success-runs chain 1000 times for various values of p and various initial states. Compare the empirical distribution to the invariant distribution.

# Time Reversal

You probably have already noticed similarities, in notation and results, between the success-runs chain and the remaining-life chain. There are deeper connections.

Suppose that *f* is a probability density function on  $\mathbb{N}$  with f(n) > 0 for  $n \in \mathbb{N}$ . Let *X* be the success-runs chain associated with *f* and *Y* the remaining life chain associated with *f*. Then *X* and *Y* are time reversals of each other. Proof

Under the assumptions on f, both chains are recurrent and irreducible. Hence it suffices to show that

$$r(x)P(x,y) = r(y)Q(y,x), \quad x, y \in \mathbb{N}$$
 (16.10.8)

It will then follow that the chains are time reversals of each other, and that r is a common invariant function (unique up to multiplication by positive constants). In the case that  $\mu = \sum_{n=0}^{\infty} r(n) < \infty$ , the function  $g = r/\mu$  is the common invariant PDF. There are only two cases to consider. With y = 0, we have r(x)P(x, 0) = r(x)[1-p(x)] and r(0)Q(y, 0) = f(x). But r(x)[1-p(x)] = f(x) by the result above. When  $x \in \mathbb{N}$  and y = x + 1, we have r(x)P(x, x+1) = r(x)p(x) and r(x+1)Q(x+1, x) = r(x+1). But r(x)p(x) = r(x+1) by the result above.

In the context of reliability, it is also easy to see that the chains are time reversals of each other. Consider again a device whose random lifetime takes values in  $\mathbb{N}$ , with the device immediately replaced by an identical device upon failure. For  $n \in \mathbb{N}$ , we can think of  $X_n$  as the age of the device in service at time n and  $Y_n$  as the time remaining until failure for that device.

Run the simulation of the success-runs chain 1000 times for various values of p, starting in state 0. This is the time reversal of the simulation in the next exercise

Run the simulation of the remaining-life chain 1000 times for various values of p, starting in state 0. This is the time reversal of the simulation in the previous exercise.

# 16.11: Discrete-Time Branching Chain

# **Basic Theory**

# Introduction

Generically, suppose that we have a system of *particles* that can generate or split into other particles of the same type. Here are some typical examples:

- The particles are biological organisms that reproduce.
- The particles are neutrons in a chain reaction.
- The particles are electrons in an electron multiplier.

We assume that each particle, at the end of its life, is replaced by a random number of new particles that we will refer to as *children* of the original particle. Our basic assumption is that the particles act independently, each with the same offspring distribution on  $\mathbb{N}$ . Let f denote the common probability density function of the number of offspring of a particle. We will also let  $f^{*n} = f * f * \cdots * f$  denote the convolution power of degree n of f; this is the probability density function of the total number of children of n particles.

We will consider the evolution of the system in *real* time in our study of continuous-time branching chains. In this section, we will study the evolution of the system in *generational* time. Specifically, the particles that we start with are in generation 0, and recursively, the children of a particle in generation n are in generation n + 1.

Figure 16.11.1: Generations 0, 1, 2, and 3 of a branching chain.

Let  $X_n$  denote the number of particles in generation  $n \in \mathbb{N}$ . One way to construct the process mathematically is to start with an array of independent random variables  $(U_{n,i} : n \in \mathbb{N}, i \in \mathbb{N}_+)$ , each with probability density function f. We interpret  $U_{n,i}$  as the number of children of the *i*th particle in generation n (if this particle exists). Note that we have more random variables than we need, but this causes no harm, and we know that we can construct a probability space that supports such an array of random variables. We can now define our state variables recursively by

$$X_{n+1} = \sum_{i=1}^{X_n} U_{n,i} \tag{16.11.1}$$

 $X = (X_0, X_1, X_2, ...)$  is a discrete-time Markov chain on  $\mathbb{N}$  with transition probability matrix P given by

$$P(x,y) = f^{*x}(y), \quad (x,y) \in \mathbb{N}^2$$
 (16.11.2)

The chain X is the *branching chain* with offspring distribution defined by f.

Proof

The Markov property and the form of the transition matrix follow directly from the construction of the state variables given above. Since the variables  $(U_{n,i} : n \in \mathbb{N}, i \in \mathbb{N}_+)$  are independent, each with PDF f, we have

$$\mathbb{P}(X_{n+1} = y \mid X_0 = x_0, \dots, X_{n-1} = x_{n-1}, X_n = x) = \mathbb{P}\left(\sum_{i=1}^x U_{n,i} = y\right) = f^{*x}(y)$$
(16.11.3)

The branching chain is also known as the *Galton-Watson process* in honor of Francis Galton and Henry William Watson who studied such processes in the context of the survival of (aristocratic) family names. Note that the descendants of each initial particle form a branching chain, and these chains are independent. Thus, the branching chain starting with x particles is equivalent to x independent copies of the branching chain starting with 1 particle. This features turns out to be very important in the analysis of the chain. Note also that 0 is an absorbing state that corresponds to *extinction*. On the other hand, the population may grow to infinity, sometimes called *explosion*. Computing the probability of extinction is one of the fundamental problems in branching chains; we will essentially solve this problem in the next subsection.

# Extinction and Explosion

The behavior of the branching chain in expected value is easy to analyze. Let m denote the mean of the offspring distribution, so that

$$m = \sum_{x=0}^{\infty} x f(x)$$
 (16.11.4)

Note that  $m \in [0, \infty]$ . The parameter *m* will turn out to be of fundamental importance.

#### Expected value properties

1.  $\mathbb{E}(X_{n+1}) = m\mathbb{E}(X_n)$  for  $n \in \mathbb{N}$ 2.  $\mathbb{E}(X_n) = m^n \mathbb{E}(X_0)$  for  $n \in \mathbb{N}$ 3.  $\mathbb{E}(X_n) \to 0$  as  $n \to \infty$  if m < 1. 4.  $\mathbb{E}(X_n) = \mathbb{E}(X_0)$  for each  $n \in \mathbb{N}$  if m = 1. 5.  $\mathbb{E}(X_n) \to \infty$  as  $n \to \infty$  if m > 1 and  $\mathbb{E}(X_0) > 0$ .

# Proof

For part (a) we use a conditioning argument and the construction above. For  $x \in \mathbb{N}$ ,

$$\mathbb{E}(X_{n+1} \mid X_n = x) = \mathbb{E}\left(\sum_{i=1}^x U_{n,i} \mid X_n = x\right) = \mathbb{E}\left(\sum_{i=1}^x U_{n,i}\right) = mx$$
(16.11.5)

That is,  $\mathbb{E}(X_{n+1} \mid X_n) = mX_n$  so  $\mathbb{E}(X_{n+1}) = \mathbb{E}[\mathbb{E}(X_{n+1} \mid X_n)] = m\mathbb{E}(X_n)$  Part (b) follows from (a) and then parts (c), (d), and (e) follow from (b).

#### Part (c) is extinction in the mean; part (d) is stability in the mean; and part (e) is explosion in the mean.

Recall that state 0 is absorbing (there are no particles), and hence  $\{X_n = 0 \text{ for some } n \in \mathbb{N}\} = \{\tau_0 < \infty\}$  is the *extinction* event (where as usual,  $\tau_0$  is the time of the first return to 0). We are primarily concerned with the probability of extinction, as a function of the initial state. First, however, we will make some simple observations and eliminate some trivial cases.

Suppose that f(1) = 1, so that each particle is replaced by a single new particle. Then

1. Every state is absorbing.

2. The equivalence classes are the singleton sets.

3. With probability 1,  $X_n = X_0$  for every  $n \in \mathbb{N}$ .

Proof

These properties are obvious since P(x, x) = 1 for every  $x \in \mathbb{N}$ .

Suppose that f(0) > 0 so that with positive probability, a particle will die without offspring. Then

1. Every state leads to 0.

2. Every positive state is transient.

3. With probability 1 either  $X_n=0$  for some  $n\in\mathbb{N}$  (extinction) or  $X_n o\infty$  as  $n o\infty$  (explosion).

Proof

1. Note that  $P(x,0) = [f(0)]^x > 0$  for  $x \in \mathbb{N}$ , so every state leads to 0 in one step.

# .ibreTexts

- 2. This follows from (a). If  $x \in \mathbb{N}_+$ , then x leads to the absorbing state 0 with positive probability. Hence a return to x, starting in x, cannot have probability 1.
- 3. This follows from (a) and (b). With probability 1, every positive state is visited only finitely many times. Hence the only possibilities are  $X_n=0$  for some  $n\in\mathbb{N}$  or  $X_n o\infty$  as  $n o\infty$  .

Suppose that f(0) = 0 and f(1) < 1, so that every particle is replaced by at least one particle, and with positive probability, more than one. Then

1. Every positive state is transient.

2.  $\mathbb{P}(X_n \to \infty \text{ as } n \to \infty \mid X_0 = x) = 1$  for every  $x \in \mathbb{N}_+$ , so that explosion is certain, starting with at least one particle.

Proof

- 1. Let  $x \in \mathbb{N}_+$ . Under the assumptions on f, state x leads to some state y > x but y does not lead back to x. Hence with positive probability, the chain starting in x will not return to x.
- 2. This follows from (a) and that the fact that positive states do not lead to 0.

Suppose that f(0) > 0 and f(0) + f(1) = 1, so that with positive probability, a particle will die without offspring, and with probability 1, a particle is not replaced by more than one particle. Then

- 1. Every state leads to 0.
- 2. Every positive state is transient.
- 3. With probability 1,  $X_n = 0$  for some  $n \in \mathbb{N}$ , so extinction is certain.

Proof

1. As before,  $P(x, 0) = [f(0)]^x > 0$  for  $x \in \mathbb{N}$ , so x leads to 0 in one step.

- 2. This follows from (a) and the fact that 0 is absorbing.
- 3. Under the assumptions on f, state x leads to state y only if  $y \le x$ . So this follows from (a) and (b).

Thus, the interesting case is when f(0) > 0 and f(0) + f(1) < 1, so that with positive probability, a particle will die without offspring, and also with positive probability, the particle will be replaced by more than one new particles. We will assume these conditions for the remainder of our discussion. By the state classification above all states lead to 0 (extinction). We will denote the probability of extinction, starting with one particle, by

$$q=\mathbb{P}( au_0<\infty\mid X_0=1)=\mathbb{P}(X_n=0 ext{ for some }n\in\mathbb{N}\mid X_0=1)$$
(16.11.6)

The set of positive states  $\mathbb{N}_+$  is a transient equivalence class, and the probability of extinction starting with  $x \in \mathbb{N}$  particles is

$$q^x = \mathbb{P}( au_0 < \infty \mid X_0 = x) = \mathbb{P}(X_n = 0 ext{ for some } n \in \mathbb{N} \mid X_0 = x)$$
 (16.11.7)

Proof

Under the assumptions on f, from any positive state the chain can move 2 or more units to the right and one unit to the left in one step. It follows that every positive state leads to every other positive state. On the other hand, every positive state leads to 0, which is absorbing. Thus,  $\mathbb{N}_+$  is a transient equivalence class.

Recall that the branching chain starting with  $x \in \mathbb{N}_+$  particles acts like x independent branching chains starting with one particle. Thus, the extinction probability starting with x particles is  $q^x$ .

The parameter *q* satisfies the equation

$$q = \sum_{x=0}^{\infty} f(x)q^x$$
 (16.11.8)

Proof

This result follows from conditioning on the first state.

$$q = \mathbb{P}( au_0 < \infty \mid X_0 = 1) = \sum_{x=0}^{\infty} \mathbb{P}( au_0 < \infty \mid X_0 = 1, X_1 = x) \mathbb{P}(X_1 = x \mid X_0 = 1)$$
 (16.11.9)

But by the Markov property and the previous result,

$$\mathbb{P}( au_0 < \infty \mid X_0 = 1, X_1 = x) = \mathbb{P}( au_0 < \infty \mid X_1 = x) = q^x$$
 (16.11.10)

and of course  $\mathbb{P}(X_1=x\mid X_0=1)=P(1,x)=f(x)$  .

Thus the extinction probability q starting with 1 particle is a *fixed point* of the probability generating function  $\Phi$  of the offspring distribution:

$$\Phi(t) = \sum_{x=0}^{\infty} f(x) t^x, \quad t \in [0,1]$$
(16.11.11)

Moreover, from the general discussion of hitting probabilities in the section on recurrence and transience, q is the smallest such number in the interval (0, 1]. If the probability generating function  $\Phi$  can be computed in closed form, then q can sometimes be computed by solving the equation  $\Phi(t) = t$ .

 $\Phi$  satisfies the following properties:

1.  $\Phi(0) = f(0)$ . 2.  $\Phi(1) = 1$ . 3.  $\Phi'(t) > 0$  for  $t \in (0, 1)$  so  $\Phi$  in increasing on (0, 1). 4.  $\Phi''(t) > 0$  for  $t \in (0, 1)$  so  $\Phi$  in concave upward on (0, 1). 5.  $m = \lim_{t \uparrow 1} \Phi'(t)$ .

Proof

These are basic properties of the probability generating function. Recall that the series that defines  $\Phi$  is a power series about 0 with radius of convergence  $r \ge 1$ . A function defined by a power series is infinitely differentiable within the open interval of convergence, and the derivates can be computed term by term. So

$$egin{aligned} \Phi'(t) &= \sum_{x=1}^\infty x f(x) t^{x-1} > 0, \quad t \in (0,1) \ \Phi''(t) &= \sum_{x=2}^\infty x (x-1) f(x) t^{x-2} > 0, \quad t \in (0,1) \end{aligned}$$

If r>1 then  $m=\Phi'(1)$  . If r=1 , the limit result is the best we can do.

Our main result is next, and relates the extinction probability q and the mean of the offspring distribution m.

The extinction probability q and the mean of the offspring distribution m are related as follows:

1. If  $m \leq 1$  then q = 1, so extinction is certain.

2. If m > 1 then 0 < q < 1, so there is a positive probability of extinction and a positive probability of explosion.

Proof

Figure 16.11.3 The case of possible extinction and possible explosion.

# **Computational Exercises**

Consider the branching chain with offspring probability density function f given by f(0) = 1 - p, f(2) = p, where  $p \in (0, 1)$  is a parameter. Thus, each particle either dies or splits into two new particles. Find each of the following.

- 1. The transition matrix *P*.
- 2. The mean m of the offspring distribution.
- 3. The generating function  $\Phi$  of the offspring distribution.
- 4. The extinction probability q.

# Answer

Note that an offspring variable has the form 2I where I is an indicator variable with parameter p.

1. For  $x \in \mathbb{N}$ ,  $f^{*x}$  is the PDF of 2U where U has the binomial distribution with parameters x and p. Hence

$$P(x,y)=f^{*x}(y)=inom{x}{y/2}p^{y/2}(1-p)^{x-y/2},\quad y\in\{0,2,\ldots,2x\}$$
 (16.11.12)

 $\begin{array}{l} 2. \ m = 2p. \\ 3. \ \Phi(t) = pt^2 + (1-p) \quad \text{for } t \in \mathbb{R}. \\ 4. \ q = 1 \ \text{ if } 0$ 

Graphs of  $t \mapsto \Phi(t)$  and  $t \mapsto t$  when  $p = \frac{1}{3}$ Graphs of  $t \mapsto \Phi(t)$  and  $t \mapsto t$  when  $p = \frac{2}{3}$ Graphs

Consider the branching chain whose offspring distribution is the geometric distribution on  $\mathbb{N}$  with parameter 1-p, where  $p \in (0, 1)$ . Thus  $f(n) = (1-p)p^n$  for  $n \in \mathbb{N}$ . Find each of the following:

1. The transition matrix *P*.

- 2. The mean m of the offspring distribution.
- 3. The generating function  $\Phi$  of the offspring distribution.

# 4. The extinction probability q.

Answer

1. For  $x \in \mathbb{N}$ ,  $f^{*x}$  is the PDF of the negative binomial distribution on  $\mathbb{N}$  with parameter 1 - p. So

$$P(x,y) = f^{*x}(y) = \binom{x+y-1}{x-1} p^y (1-p)^x, \quad y \in \mathbb{N}$$
(16.11.13)

 $\begin{array}{l} 2. \ m = \frac{p}{1-p} \, . \\ 3. \ \Phi(t) = \frac{1-p}{1-pt} \ \text{for} \ |t| < \frac{1}{p} \, . \\ 4. \ q = 1 \ \text{ if } 0 < p \leq \frac{1}{2} \ \text{ and } q = \frac{1-p}{p} \ \text{ if } \frac{1}{2} < p < 1 \ . \end{array}$ 

$$\begin{array}{c} \text{Graphs of } t\mapsto \Phi(t) \text{ and } t\mapsto t \text{ when } p=\frac{1}{3} \\ & & & & \\ & & & \\ \text{Graphs} \end{array}$$

$$\text{Graphs of } t\mapsto \Phi(t) \text{ and } t\mapsto t \text{ when } p=\frac{2}{3} \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ \end{array}$$

Curiously, the extinction probability is the same as for the previous problem.

Consider the branching chain whose offspring distribution is the Poisson distribution with parameter  $m \in (0, \infty)$ . Thus  $f(n) = e^{-m}m^n/n!$  for  $n \in \mathbb{N}$ . Find each of the following:

1. The transition matrix P.

2. The mean m of the offspring distribution.

3. The generating function  $\Phi$  of the offspring distribution.

4. The approximate extinction probability q when m = 2 and when m = 3.

Answer

1. For  $x \in \mathbb{N}$ ,  $f^{*x}$  is the PDF of the Poisson distribution with parameter mx. So

$$P(x,y) = f^{*x}(y) = e^{-mx} \frac{(mx)^y}{y!}, \quad y \in \mathbb{N}$$
 (16.11.14)

2. The parameter m is the mean of the Poisson distribution, so the notation is consistent.

3.  $\Phi(t) = e^{m(t-1)}$  for  $t \in \mathbb{R}$ .

4. q = 1 if  $0 < m \le 1$ . If m > 1 then q is the solution in (0, 1) of the equation  $e^{m(q-1)} = q$  which can be expressed in terms of a special function known as the *Lambert W function*:

$$q = -\frac{1}{m}W\left(-me^{-m}\right)$$
(16.11.15)

For  $m = 2, q \approx 0.20319$ . For  $m = 3, q \approx 0.059520$ 

This page titled 16.11: Discrete-Time Branching Chain is shared under a CC BY 2.0 license and was authored, remixed, and/or curated by Kyle Siegrist (Random Services) via source content that was edited to the style and standards of the LibreTexts platform.

# 16.12: Discrete-Time Queuing Chains

# **Basic Theory**

# Introduction

In a *queuing model*, *customers* arrive at a station for *service*. As always, the terms are generic; here are some typical examples:

- The customers are persons and the service station is a store.
- The customers are file requests and the service station is a web server.
- The customers are packages and the service station is a processing facility.

<b>* * * *</b>	<b>*</b>	<b>†</b>	<b>*</b>   <b>*</b>	1
----------------	----------	----------	---------------------	---

Figure 16.12.1: Ten customers and a server

Queuing models can be quite complex, depending on such factors as the probability distribution that governs the arrival of customers, the probability distribution that governs the service of customers, the number of servers, and the behavior of the customers when all servers are busy. Indeed, queuing theory has its own lexicon to indicate some of these factors. In this section, we will study one of the simplest, discrete-time queuing models. However, as we will see, this discrete-time chain is embedded in a much more realistic continuous-time queuing process knows as the M/G/1 queue. In a general sense, the main interest in any queuing model is the number of customers in the system as a function of time, and in particular, whether the servers can adequately handle the flow of customers.

Our main assumptions are as follows:

- 1. If the queue is empty at a given time, then a random number of new customers arrive at the next time.
- 2. If the queue is nonempty at a given time, then one customer is served and a random number of new customers arrive at the next time.
- 3. The number of customers who arrive at each time period form an independent, identically distributed sequence.

Thus, let  $X_n$  denote the number of customers in the system at time  $n \in \mathbb{N}$ , and let  $U_n$  denote the number of new customers who arrive at time  $n \in \mathbb{N}_+$ . Then  $U = (U_1, U_2, ...)$  is a sequence of independent random variables, with common probability density function f on  $\mathbb{N}$ , and

$$X_{n+1} = \begin{cases} U_{n+1}, & X_n = 0\\ (X_n - 1) + U_{n+1}, & X_n > 0 \end{cases}, \quad n \in \mathbb{N}$$
(16.12.1)

 $X = (X_0, X_1, X_2, ...)$  is a discrete-time Markov chain with state space  $\mathbb{N}$  and transition probability matrix P given by

$$P(0,y) = f(y), \quad y \in \mathbb{N}$$
(16.12.2)
$$P(y,y) = f(y,y) = f(y,y)$$

$$P(x,y) = f(y-x+1), \quad x \in \mathbb{N}_+, \ y \in \{x-1,x,x+1,\ldots\}$$
 (16.12.3)

The chain X is the *queuing chain* with arrival distribution defined by f.

Proof

The Markov property and the form of the transition matrix follow from the construction of the state process X in term of the IID sequence U. Starting in state 0 (an empty queue), a random number of new customers arrive at the next time unit, governed by the PDF f. Hence the probability of going from state 0 to state y in one step is f(y). Starting in state  $x \in \mathbb{N}_+$ , one customer is served and a random number of new customers arrive by the next time unit, again governed by the PDF f. Hence the probability of going from state  $y \in \{x - 1, x, x + 1, ...\}$  is f[y - (x - 1)].

## **Recurrence and Transience**

From now on we will assume that f(0) > 0 and f(0) + f(1) < 1. Thus, at each time unit, it's possible that no new customers arrive or that at least 2 new customers arrive. Also, we let *m* denote the mean of the arrival distribution, so that

$$n = \sum_{x=0}^{\infty} x f(x)$$
 (16.12.4)

Thus m is the average number of new customers who arrive during a time period.

The chain  $\boldsymbol{X}$  is irreducible and aperiodic.

Proof

In a positive state, the chain can move at least one unit to the right and can move one unit to the left at the next step. From state 0, the chain can move two or more units to the right or can stay in 0 at the next step. Thus, every state leads to every other state so the chain is irreducible. Since 0 leads back to 0, the chain is aperiodic.

1

Our goal in this section is to compute the probability that the chain reaches 0, as a function of the initial state (so that the server is able to serve all of the customers). As we will see, there are some curious and unexpected parallels between this problem and the problem of computing the extinction probability in the branching chain. As a corollary, we will also be able to classify the queuing chain as transient or recurrent. Our basic parameter of interest is  $q = H(1, 0) = \mathbb{P}(\tau_0 < \infty \mid X_0 = 1)$ , where as usual, H is the hitting probability matrix and  $\tau_0 = \min\{n \in \mathbb{N}_+ : X_n = 0\}$  is the first positive time that the chain is in state 0 (possibly infinite). Thus, q is the probability that the queue eventually empties, starting with a single customer.

The parameter q satisifes the following properties:

1.  $q=H(x,x-1)\,$  for every  $x\in \mathbb{N}_+$  .

2. 
$$q^x = H(x, 0)$$
 for every  $x \in \mathbb{N}_+$  .

Proof

- 1. The critical observation is that if  $x\in\mathbb{N}_+$  then P(x,y)=P(1,y-x+1)=f(y-x+1) for
- $y \in \{x 1, x, x + 1, ...\}$ . Thus, the chain, starting in x, and up until the time that it reaches x 1 (if it does), behaves stochastically like the chain starting in state 1, and up until it reaches 0.
- 2. In order to reach 0, starting in state  $x \in \mathbb{N}_+$ , the chain must first reach x 1 and then from x 1 must reach x 2, until finally reaching 0 from state 1. Each of these intermediate trips has probability q by part (a) and are independent by the Markov property.

The parameter q satisfies the equation:

$$q = \sum_{x=0}^{\infty} f(x)q^x$$
 (16.12.5)

Proof

This follows from the previous theorem by conditioning on the first state.

$$\mathbb{P}(\tau_0 < \infty \mid X_0 = 1) = \sum_{x=0}^{\infty} \mathbb{P}(\tau_0 < \infty \mid X_0 = 1, X_1 = x) \mathbb{P}(X_1 = x \mid X_0 = 1) \tag{16.12.6}$$

Note first that  $\mathbb{P}( au_0 < \infty \mid X_0 = 1, X_1 = 0) = 1 = q^0$  . On the other hand, by the Markov property and the previous result,

$$\mathbb{P}(\tau_0 < \infty \mid X_0 = 1, X_1 = x) = \mathbb{P}(\tau_0 < \infty \mid X_1 = x) = q^x, \quad x \in \mathbb{N}_+$$
(16.12.7)

Of course 
$$\mathbb{P}(X_1=x\mid X_0=1)=P(1,x)=f(x)$$
 for  $x\in\mathbb{N}$  .

Note that this is exactly the same equation that we considered for the branching chain, namely  $\Phi(q) = q$ , where  $\Phi$  is the probability generating function of the distribution that governs the number of new customers that arrive during each period.

Figure 16.12.3 The graph of  $\phi$  in the transient case

q is the smallest solution in (0,1] of the equation  $\Phi(t) = t$  . Moreover

- 1. If  $m \leq 1$  then q = 1 and the chain is recurrent.
- 2. If m > 1 then 0 < q < 1 and the chain is transient.

# Proof

This follows from our analysis of branching chains. The graphs above show the two cases. Note that the condition in (a) means that on average, one or fewer new customers arrive for each customer served. The condition in (b) means that on average, more than one new customer arrives for each customer served.

## **Positive Recurrence**

Our next goal is to find conditions for the queuing chain to be positive recurrent. Recall that m is the mean of the probability density function f; that is, the expected number of new customers who arrive during a time period. As before, let  $\tau_0$  denote the first positive time that the chain is in state 0. We assume that the chain is recurrent, so  $m \leq 1$  and  $\mathbb{P}(\tau_0 < \infty) = 1$ .

Let  $\Psi$  denote the probability generating function of  $\tau_0$ , starting in state 1. Then

- 1.  $\Psi$  is also the probability generating function of  $\tau_0$  starting in state 0.
- 2.  $\Psi^x$  is the probability generating function of  $au_0$  starting in state  $x \in \mathbb{N}_+$  .

# Proof

- 1. The transition probabilities starting in state 1 are the same as those starting in state 0: P(0, x) = P(1, x) = f(x) for  $x \in \mathbb{N}$ .
- 2. Starting in state  $x \in \mathbb{N}_+$ , the random time to reach 0 is the sum of the time to reach x 1, the additional time to reach x 2 from x 1, and so forth, ending with the time to reach 0 from state 1. These random times are independent by the Markov property, and each has the same distribution as the time to reach 0 from state 1 by our argument above. Finally, recall that the PGF of a sum of independent variables is the product of the corresponding PGFs.

```
\Psi(t) = t\Phi[\Psi(t)] 	ext{ for } t \in [-1,1].
```

Proof

Once again, the trick is to condition on the first state:

$$\Psi(t) = \mathbb{E}\left(t^{\tau_0} \mid X_0 = 1\right) = \sum_{x=0}^{\infty} \mathbb{E}\left(t^{\tau_0} \mid X_0 = 1, X_1 = x\right) \mathbb{P}(X_1 = x \mid X_0 = 1)$$
(16.12.8)

First note that  $\mathbb{E}(t^{\tau_0} | X_0 = 1, X_1 = 0) = t^1 = t\Psi^0(t)$ . On the other hand, by the Markov property and the previous theorem,

$$\mathbb{E}\left(t^{\tau_{0}} \mid X_{0} = 1, X_{1} = x\right) = \mathbb{E}\left(t^{1+\tau_{0}} \mid X_{0} = x\right) = t\mathbb{E}\left(t^{\tau_{0}} \mid X_{0} = x\right) = t\Psi^{x}(t), \quad x \in \mathbb{N}_{+}$$
(16.12.9)

Of course  $\mathbb{P}(X_1=x\mid X_0=1)=P(1,x)=f(x)~$  . Hence we have

$$\Psi(t) = \sum_{x=0}^{\infty} t \Psi^x(t) f(x) = t \Phi[\Psi(t)]$$
(16.12.10)

The PGF of any variable that takes positive integer values is defined on [-1, 1], and maps this interval back into itself. Hence the representation is valid at least for  $t \in [-1, 1]$ .

The deriviative of  $\Psi$  is

$$\Psi'(t) = \frac{\Phi[\Psi(t)]}{1 - t\Phi'[\Psi(t)]}, \quad t \in (-1, 1)$$
(16.12.11)

Proof

Recall that a PGF is infinitely differentiable on the open interval of convergence. Hence using the result in the previous theorem and the product and chain rules,

$$\Psi'(t) = \Phi[\Psi(t)] + t\Phi'[\Psi(t)]\Psi'(t)$$
(16.12.12)

Solving for  $\Psi'(t)$  gives the result.

As usual, let  $\mu_0 = \mathbb{E}( au_0 \mid X_0 = 0)$  , the mean return time to state 0 starting in state 0. Then

1.  $\mu_0 = \frac{1}{1-m}$  if m < 1 and therefore the chain is positive recurrent.

2.  $\mu_0 = \infty$  if m = 1 and therefore the chain is null recurrent.

Proof

Recall that  $\Psi$  is the probability generating function of  $\tau_0$ , starting at 0. From basic properties of PGFs we know that  $\Phi(t) \uparrow 1$ ,  $\Psi(t) \uparrow 1$ ,  $\Phi'(t) \uparrow m$ , and  $\Psi'(t) \uparrow \mu_0$  as  $t \uparrow 1$ . So letting  $t \uparrow 1$  in the result of the previous theorem, we have  $\mu_0 = 1/(1-m)$  if m < 1 and  $\mu_0 = \infty$  if m = 1.

So to summarize, the queuing chain is positive recurrent if m < 1, null recurrent if m = 1, and transient if m > 1. Since m is the expected number of new customers who arrive during a service period, the results are certainly reasonable.

# **Computational Exercises**

Consider the queuing chain with arrival probability density function f given by f(0) = 1 - p, f(2) = p, where  $p \in (0, 1)$  is a parameter. Thus, at each time period, either no new customers arrive or two arrive.

- 1. Find the transition matrix *P*.
- 2. Find the mean m of the arrival distribution.
- 3. Find the generating function  $\Phi$  of the arrival distribution.
- 4. Find the probability *q* that the queue eventually empties, starting with one customer.
- 5. Classify the chain as transient, null recurrent, or positive recurrent.
- 6. In the positive recurrent case, find  $\mu_0$ , the mean return time to 0.

Answer

1. 
$$P(0,0)=1-p$$
 ,  $P(0,2)=p.$  For  $x\in\mathbb{N}_+$  ,  $P(x,x-1)=1-p$  ,  $P(x,x+1)=p$  . 2.  $m=2p.$ 

3.  $\Phi(t) = pt^2 + (1-p)$  for  $t \in \mathbb{R}$ . 4. q = 1 if  $0 and <math>q = \frac{1-p}{p}$  if  $\frac{1}{2} .$  $5. The chain is transient if <math>p > \frac{1}{2}$ , null recurrent if  $p = \frac{1}{2}$ , and positive recurrent if  $p < \frac{1}{2}$ . 6.  $\mu_0 = \frac{1}{1-2p}$  for  $p < \frac{1}{2}$ . Graphs of  $t \mapsto \Phi(t)$  and  $t \mapsto t$  when  $p = \frac{1}{3}$ Graphs of  $t \mapsto \Phi(t)$  and  $t \mapsto t$  when  $p = \frac{2}{3}$ 

Consider the queuing chain whose arrival distribution is the geometric distribution on  $\mathbb{N}$  with parameter 1-p, where  $p \in (0, 1)$ . Thus  $f(n) = (1-p)p^n$  for  $n \in \mathbb{N}$ .

- 1. Find the transition matrix *P*.
- 2. Find the mean m of the arrival distribution.
- 3. Find the generating function  $\Phi$  of the arrival distribution.
- 4. Find the probability *q* that the queue eventually empties, starting with one customer.
- 5. Classify the chain as transient, null recurrent, or positive recurrent.
- 6. In the positive recurrent case, find  $\mu_0$ , the mean return time to 0.

#### Answer

1. 
$$P(0, y) = (1-p)p^y$$
 for  $y \in \mathbb{N}$ . For  $x \in \mathbb{N}_+$ ,  $P(x, y) = (1-p)p^{y-x+1}$  for  $y \in \{x-1, x, x+1, \ldots\}$ .  
2.  $m = \frac{p}{1-p}$ .  
3.  $\Phi(t) = \frac{1-p}{1-pt}$  for  $|t| < \frac{1}{p}$ .  
4.  $q = 1$  if  $0 and  $q = \frac{1-p}{p}$  if  $\frac{1}{2} .
5. The chain is transient if  $p > \frac{1}{2}$ , null recurrent if  $p = \frac{1}{2}$ , and positive recurrent if  $p < \frac{1}{2}$ .  
6.  $\mu_0 = \frac{1-p}{1-2p}$  for  $p < \frac{1}{2}$ .  
Graphs of  $t \mapsto \Phi(t)$  and  $t \mapsto t$  when  $p = \frac{1}{3}$   
Graphs of  $t \mapsto \Phi(t)$  and  $t \mapsto t$  when  $p = \frac{2}{3}$$$ 

Curiously, the parameter q and the classification of the chain are the same in the last two models.

Consider the queuing chain whose arrival distribution is the Poisson distribution with parameter  $m \in (0, \infty)$ . Thus  $f(n) = e^{-m}m^n/n!$  for  $n \in \mathbb{N}$ . Find each of the following:

- 1. The transition matrix  $\boldsymbol{P}$
- 2. The mean m of the arrival distribution.
- 3. The generating function  $\Phi$  of the arrival distribution.
- 4. The approximate value of *q* when m = 2 and when m = 3.
- 5. Classify the chain as transient, null recurrent, or positive recurrent.

6. In the positive recurrent case, find  $\mu_0$ , the mean return time to 0.

# Answer

1. 
$$P(0,y) = e^{-m}m^y/y!$$
 for  $y \in \mathbb{N}$ . For  $x \in \mathbb{N}_+$  ,  $P(x,y) = e^{-m}m^{y-x+1}/(y-x+1)!$  for  $y \in \{x-1,x,x+1,\ldots\}$  .

2. The parameter m is the mean of the Poisson distribution, so the notation is consistent.

3.  $\Phi(t) = e^{m(t-1)}$  for  $t \in \mathbb{R}$ .

4. q = 1 if  $0 < m \le 1$ . If m > 1 then q is the solution in (0, 1) of the equation  $e^{m(q-1)} = q$  which can be expressed in terms of a special function known as the *Lambert W function*:

$$q = -\frac{1}{m}W(-me^{-m})$$
(16.12.13)

For m=2 , qpprox 0.20319 For m=3 , qpprox 0.059520

5. The chain is transient if m > 1, null recurrent if m = 1, and positive recurrent if m < 1. 6.  $\mu_0 = \frac{1}{1-m}$  for m < 1. Graphs of  $t \mapsto \Phi(t)$  and  $t \mapsto t$  when  $m = \frac{1}{2}$ 

Graphs of 
$$t \mapsto \Psi(t)$$
 and  $t \mapsto t$  when  $m = \frac{1}{2}$   
Graphs of  $t \mapsto \Phi(t)$  and  $t \mapsto t$  when  $m = 2$   
Graphs

# 16.13: Discrete-Time Birth-Death Chains

# Basic Theory

# Introduction

Suppose that *S* is an interval of integers (that is, a set of consecutive integers), either finite or infinite. A (discrete-time) *birth*-*death* chain on *S* is a discrete-time Markov chain  $\mathbf{X} = (X_0, X_1, X_2, ...)$  on *S* with transition probability matrix *P* of the form

$$P(x, x-1) = q(x), \ P(x, x) = r(x), \ P(x, x+1) = p(x); \ x \in S$$
 (16.13.1)

where *p*, *q*, and *r* are nonnegative functions on *S* with p(x) + q(x) + r(x) = 1 for  $x \in S$ .

If the interval *S* has a minimum value  $a \in \mathbb{Z}$  then of course we must have q(a) = 0. If r(a) = 1, the boundary point *a* is *absorbing* and if p(a) = 1, then *a* is *reflecting*. Similarly, if the interval *S* has a maximum value  $b \in \mathbb{Z}$  then of course we must have p(b) = 0. If r(b) = 1, the boundary point *b* is *absorbing* and if p(b) = 1, then *b* is *reflecting*. Several other special models that we have studied are birth-death chains; these are explored in below.

In this section, as you will see, we often have sums of products. Recall that a sum over an empty index set is 0, while a product over an empty index set is 1.

## **Recurrence and Transience**

If *S* is finite, classification of the states of a birth-death chain as recurrent or transient is simple, and depends only on the state graph. In particular, if the chain is irreducible, then the chain is positive recurrent. So we will study the classification of birth-death chains when  $S = \mathbb{N}$ . We assume that p(x) > 0 for all  $x \in \mathbb{N}$  and that q(x) > 0 for all  $x \in \mathbb{N}_+$  (but of course we must have q(0) = 0). Thus, the chain is irreducible.

Under these assumptions, the birth-death chain on  $\mathbb{N}$  is

1. Aperiodic if r(x) > 0 for some  $x \in \mathbb{N}$ .

2. Periodic with period 2 if r(x) = 0 for all  $x \in \mathbb{N}$ .

Proof

1. If r(x) > 0 for some  $x \in \mathbb{N}$  then P(x, x) > 0 and hence the chain is aperiodic.

2. If r(x) = 0 for every  $x \in \mathbb{N}$  then clearly the chain starting in x can be in state x again only at even times.

We will use the test for recurrence derived earlier with  $A = \mathbb{N}_+$ , the set of positive states. That is, we will compute the probability that the chain never hits 0, starting in a positive state.

The chain  $\boldsymbol{X}$  is recurrent if and only if

$$\sum_{x=0}^{\infty} \frac{q(1)\cdots q(x)}{p(1)\cdots p(x)} = \infty$$
(16.13.2)

Proof

Let  $P_+$  denote the restriction of P to  $\mathbb{N}_+ imes \mathbb{N}_+$  , and define  $u_+: \mathbb{N}_+ o [0,1]$  by

$$u_+(x) = \mathbb{P}(X_1 > 0, X_2 > 0, \dots \mid X_0 = x), \quad x \in \mathbb{N}_+$$
 (16.13.3)

So  $u_+(x)$  is the probability that chain never reaches 0, starting in  $x \in \mathbb{N}_+$ . From our general theory, we know that  $u_+$  satisfies  $u_+ = P_+u_+$  and is the largest such function with values in [0, 1]. Furthermore, we know that either  $u_+(x) = 0$  for all  $x \in \mathbb{N}_+$  or that  $\sup\{u_+(x) : x \in [0, 1]\} = 1$ . In the first case the chain is recurrent, and in the second case the chain is transient.

The functional equation  $P_+u = u$  for a function  $u : \mathbb{N}_+ \to [0, 1]$  is equivalent to the following system of equations:

$$u(2) - u(1) = \frac{q(1)}{p(1)}u(1)$$
(16.13.4)

$$u(x+1)-u(x) = rac{q(x)}{p(x)}[u(x)-u(x-1)], \quad x\in\{2,3,\ldots\}$$
 (16.13.5)

Solving this system of equations for the differences gives

$$u(x+1) - u(x) = rac{q(1) \cdots q(x)}{p(1) \cdots p(x)} u(1), \quad x \in \mathbb{N}_+$$
 (16.13.6)

Solving this new systems gives

$$u(x) = u(1) \sum_{i=0}^{x-1} rac{q(1) \cdots q(i)}{p(1) \cdots p(i)}, \quad x \in \mathbb{N}_+$$
 (16.13.7)

Note that u(x) is increasing in  $x \in \mathbb{N}_+$  and so has a limit as  $x \to \infty$ . Let  $A = \sum_{i=0}^{\infty} \frac{q(1) \cdots q(i)}{p(1) \cdots p(i)}$ .

- 1. Suppose that  $A = \infty$ . Letting  $x \to \infty$  in the displayed equation above for u(x) shows that u(1) = 0 and so u(x) = 0 for all x. Hence the chain is recurrent.
- 2. Suppose that  $A < \infty$ . Define u(1) = 1/A and then more generally,

$$u(x) = rac{1}{A} \sum_{i=0}^{x-1} rac{q(1) \cdots q(i)}{p(1) \cdots p(i)}, \quad x \in \mathbb{N}_+$$
 (16.13.8)

The function u takes values in (0, 1) and satisfies the functional equation  $u = P_+u$ . Hence the chain is transient. Note that  $u(x) \rightarrow 1$  as  $x \rightarrow \infty$  and so in fact,  $u = u_+$ , the function that we discussed above that gives the probability of staying in  $\mathbb{N}_+$  for all time. We will return to this function below in our discussion of absorption.

Note that r, the function that assigns to each state  $x \in \mathbb{N}$  the probability of an immediate return to x, plays no direct role in whether the chain is transient or recurrent. Indeed all that matters are the ratios q(x)/p(x) for  $x \in \mathbb{N}_+$ .

#### **Positive Recurrence and Invariant Distributions**

Suppose again that we have a birth-death chain X on  $\mathbb{N}$ , with p(x) > 0 for all  $x \in \mathbb{N}$  and q(x) > 0 for all  $x \in \mathbb{N}_+$ . Thus the chain is irreducible.

The function  $g:\mathbb{N} o (0,\infty)$  defined by

$$g(x) = rac{p(0) \cdots p(x-1)}{q(1) \cdots q(x)}, \quad x \in \mathbb{N}$$
 (16.13.9)

is invariant for X, and is the only invariant function, up to multiplication by constants. Hence X is positive recurrent if and only if  $B = \sum_{x=0}^{\infty} g(x) < \infty$ , in which case the (unique) invariant probability density function f is given by  $f(x) = \frac{1}{B}g(x)$  for  $x \in \mathbb{N}$ .

Proof

Recall that by convention, a product over an empty index set is 1. So first,

$$egin{aligned} (gP)(0) &= g(0)P(0,0) + g(1)P(1,0) = g(0)r(0) + g(1)q(1) \ &= 1r(0) + rac{p(0)}{q(1)}q(1) = [1 - p(0)] + p(0) = 1 = g(0) \end{aligned}$$

Next, for  $y \in \mathbb{N}_+$ ,

$$egin{aligned} (gP)(y) &= g(y-1)P(y-1,y)+g(y)P(y,y)+g(y+1)P(y+1,y)\ &= g(y-1)p(y-1)+g(y)r(y)+g(y+1)q(y+1)\ &= g(y-1)p(y-1)+g(y)[1-p(y)-q(y)]+g(y+1)q(y+1) \end{aligned}$$

But

(†)

$$egin{aligned} g(y-1)p(y-1) &= g(y)q(y) = rac{p(0)\cdots p(y-1)}{q(1)\cdots q(y-1)} \ g(y+1)q(y+1) &= g(y)p(y) = rac{p(0)\cdots p(y)}{q(1)\cdots q(y)} \end{aligned}$$

so (gP)(y) = g(y).

Conversely, suppose that  $h : \mathbb{N} \to \mathbb{R}$  is invariant for X. We will show by induction that h(x) = h(0)g(x) for all  $x \in \mathbb{N}$ . The result is trivially true for x = 0 since g(0) = 1. Next, (hP)(0) = h(0) gives h(0)P(0,0) + h(1)P(1,0) = h(0). But P(0,0) = r(0) = [1-p(0)] and P(1,0) = q(1), so substituting and solving for h(1) gives

$$h(1) = h(0)\frac{p(0)}{q(1)} = h(0)g(1)$$
(16.13.10)

so the result is true when x = 1. Assume now that  $y \in \mathbb{N}_+$  and that the result is true for all  $x \in \mathbb{N}$  with  $x \leq y$ . Then (hP)(y) = h(y) gives

$$h(y-1)P(y-1,y) + h(y)P(y,y) + h(y+1)P(y+1,y) = h(y)$$
(16.13.11)

But P(y-1,y) = p(y-1), P(y,y) = r(y) = 1 - p(y) - q(y), and P(y+1,y) = q(y+1). Also, by the induction hypothesis, h(y) = h(0)g(y) and h(y-1) = h(0)g(y-1) so substituting and using the definition of g gives

$$egin{aligned} q(y+1)h(y+1) &= [p(y)+q(y)]h(0)rac{p(0)\cdots p(y-1)}{q(1)\cdots q(y)} - p(y-1)h(0)rac{p(0)\cdots p(y-2)}{q(1)\cdots q(y-1)} \ &= h(0)rac{p(0)\cdots p(y)}{q(1)\cdots q(y)} \end{aligned}$$

Finally, solving gives

$$h(y+1) = h(0)\frac{p(0)\cdots p(y)}{q(1)\cdots q(y+1)} = h(0)g(y+1)$$
(16.13.12)

Here is a summary of the classification:

For the birth-death chain X, define

$$A = \sum_{x=0}^{\infty} \frac{q(1)\cdots q(x)}{p(1)\cdots p(x)}, \quad B = \sum_{x=0}^{\infty} \frac{p(0)\cdots p(x-1)}{q(1)\cdots q(x)}$$
(16.13.13)

1.  $oldsymbol{X}$  is transient if  $A < \infty$ 

- 2. *X* is null recurrent if  $A = \infty$  and  $B = \infty$ .
- 3. *X* is positive recurrent if  $B < \infty$ .

Note again that r, the function that assigns to each state  $x \in \mathbb{N}$  the probability of an immediate return to x, plays no direct role in whether the chain is transient, null recurrent, or positive recurrent. Also, we know that an irreducible, recurrent chain has a positive invariant function that is unique up to multiplication by positive constants, but the birth-death chain gives an example where this is also true in the transient case.

Suppose now that  $n \in \mathbb{N}_+$  and that  $\mathbf{X} = (X_0, X_1, X_2, ...)$  is a birth-death chain on the integer interval  $\mathbb{N}_n = \{0, 1, ..., n\}$ . We assume that p(x) > 0 for  $x \in \{0, 1, ..., n-1\}$  while q(x) > 0 for  $x \in \{1, 2, ..., n\}$ . Of course, we must have q(0) = p(n) = 0. With these assumptions,  $\mathbf{X}$  is irreducible, and since the state space is finite, positive recurrent. So all that remains is to find the invariant distribution. The result is essentially the same as when the state space is  $\mathbb{N}$ .

The invariant probability density function  $f_n$  is given by

$$f_n(x) = rac{1}{B_n} rac{p(0) \cdots p(x-1)}{q(1) \cdots q(x)} ext{ for } x \in \mathbb{N}_n ext{ where } B_n = \sum_{x=0}^n rac{p(0) \cdots p(x-1)}{q(1) \cdots q(x)} ext{ (16.13.14)}$$

Proof

Define

$$g_n(x) = rac{p(0) \cdots p(x-1)}{q(1) \cdots q(x)}, \quad x \in \mathbb{N}_n$$
 (16.13.15)

The proof thet  $g_n$  is invariant for X is the same as before. The constant  $B_n$  is the normalizing constant.

Note that  $B_n \to B$  as  $n \to \infty$ , and if  $B < \infty$ ,  $f_n(x) \to f(x)$  as  $n \to \infty$  for  $x \in \mathbb{N}$ . We will see this type of behavior again. Results for the birth-death chain on  $\mathbb{N}_n$  often converge to the corresponding results for the birth-death chain on  $\mathbb{N}$  as  $n \to \infty$ .

#### Absorption

Often when the state space  $S = \mathbb{N}$ , the state of a birth-death chain represents a *population* of individuals of some sort (and so the terms *birth* and *death* have their usual meanings). In this case state 0 is absorbing and means that the population is extinct. Specifically, suppose that  $\mathbf{X} = (X_0, X_1, X_2, ...)$  is a birth-death chain on  $\mathbb{N}$  with r(0) = 1 and with p(x), q(x) > 0 for  $x \in \mathbb{N}_+$ . Thus, state 0 is absorbing and all positive states lead to each other and to 0. Let  $N = \min\{n \in \mathbb{N} : X_n = 0\}$  denote the time until absorption, where as usual,  $\min \emptyset = \infty$ .

One of the following events will occur:

1. *Population extinction*:  $N < \infty$  or equivalently,  $X_m = 0$  for some  $m \in \mathbb{N}$  and hence  $X_n = 0$  for all  $n \ge m$ .

2. Population explosion:  $N = \infty$  or equivalently  $X_n \to \infty$  as  $n \to \infty$ .

Proof

Part (b) follows from the general theory, since 0 is absorbing, and all positive states lead to each other and to 0. Thus the positive states are transient and we know that with probability 1, a Markov chain will visit a transient state only finitely often. Thus  $N = \infty$  is equivalent to  $X_n \to \infty$  as  $n \to \infty$ .

Naturally we would like to find the probability of these complementary events, and happily we have already done so in our study of recurrence above. Let

$$u(x) = \mathbb{P}(N = \infty) = \mathbb{P}(X_n o \infty ext{ as } n o \infty \mid X_0 = x), \quad x \in \mathbb{N}$$
 (16.13.16)

so the absorption probability is

$$v(x) = 1 - u(x) = \mathbb{P}(N < \infty) = \mathbb{P}(X_n = 0 \text{ for some } n \in \mathbb{N} \mid X_0 = x), \quad x \in \mathbb{N}$$
 (16.13.17)

For the birth-death chain  $\boldsymbol{X}$ ,

$$u(x) = \frac{1}{A} \sum_{i=0}^{x-1} \frac{q(1) \cdots q(i)}{p(1) \cdots p(i)} \text{ for } x \in \mathbb{N}_+ \text{ where } A = \sum_{i=0}^{\infty} \frac{q(1) \cdots q(i)}{p(1) \cdots p(i)}$$
(16.13.18)

Proof

For  $x \in \mathbb{N}_+$ , note that  $u(x) = \mathbb{P}(X_n \in \mathbb{N}_+ \text{ for all } n \in \mathbb{N} \mid X_0 = x)$ , the function that gives the probability of staying in the positive states for all time. The proof of the theorem on recurrence above has nothing to do with the transition probabilities in state 0, so the proof applies in this setting as well. In that proof we showed that u(x) as the form given above, where of course the value is 0 if  $A = \infty$ . Trivially, u(0) = 0.

So if  $A = \infty$  then u(x) = 0 for all  $x \in S$ . If  $A < \infty$  then u(x) > 0 for all  $x \in \mathbb{N}_+$  and  $u(x) \to 1$  as  $x \to \infty$ . For the absorption probability, v(x) = 1 for all  $x \in \mathbb{N}$  if  $A = \infty$  and so absorption is certain. If  $A < \infty$  then

$$v(x) = rac{1}{A}\sum_{i=x}^{\infty}rac{q(1)\cdots q(i)}{p(1)\cdots p(i)}, \quad x\in\mathbb{N}$$
 (16.13.19)

Next we consider the mean time to absorption, so let  $m(x) = \mathbb{E}(N \mid X_0 = x)$  for  $x \in \mathbb{N}_+$ .

The mean absorption function is given by

$$m(x) = \sum_{j=1}^{x} \sum_{k=j-1}^{\infty} rac{p(j) \cdots p(k)}{q(j) \cdots q(k+1)}, \quad x \in \mathbb{N}$$
 (16.13.20)

#### Probabilisitic Proof

The number of steps required to go from state  $x \in \mathbb{N}_+$  to x - 1 has the same distribution as the number of steps required to go from state 1 to 0, except with parameters p(y), q(y) for  $y \in \{x, x + 1, \ldots\}$  instead of parameters p(y), q(y) for  $y \in \{1, 2, \ldots\}$ . So by the additivity of expected value, we just need to compute m(1) as a function of the parameters. Starting in state 1, the chain will be absorbed in state 0 after a random number of returns to state 1 without absorption. Whenever the chain is in state 1, absorption occurs at the next time with probability q(1) so it follows that the number of times that the chain is in state 1 before absorption has the geometric distribution on  $\mathbb{N}_+$  with success parameter q(1). The mean of this distribution is 1/q(1). On the other hand, starting in state 1, the number of steps until the chain is in state 1 again (without absorption) has the same distribution as the return time to state 0, starting in state 0 for the irreducible birth-death chain  $\mathbf{X}'$  considered above but with birth and death functions p' and q' given by p'(x) = p(x+1) for  $x \in \mathbb{N}$  and q'(x) = q(x+1) for  $x \in \mathbb{N}_+$ . Thus, let

$$\mu = \sum_{k=0}^{\infty} \frac{p(1)\cdots p(k)}{q(2)\cdots q(k+1)}$$
(16.13.21)

Then  $\mu$  is the mean return time to state 0 for the chain X'. Specifically, note that if  $\mu = \infty$  then X' is either transient or null recurrent. If  $\mu < \infty$  then  $1/\mu$  is the invariant PDF at 0. So, it follows that

$$m(1) = \frac{1}{q(1)}\mu = \sum_{k=0}^{\infty} \frac{p(1)\cdots p(k)}{q(1)\cdots q(k+1)}$$
(16.13.22)

By our argument above, the mean time to go from state x to x - 1 is

$$\sum_{k=x-1}^{\infty} \frac{p(x)\cdots p(k)}{q(x)\cdots q(k+1)}$$
(16.13.23)

Analytic Proof

Conditioning and using the Markov property, we have

$$m(x) = 1 + p(x)m(x+1) + q(x)m(x-1) + r(x)m(x), \quad x \in \mathbb{N}_+$$
(16.13.24)

with initial condition m(0) = 0. Equivalently,

$$m(x+1)-m(x)=rac{q(x)}{p(x)}[m(x)-m(x-1)]-rac{1}{p(x)}, \quad x\in\mathbb{N}_+$$
 (16.13.25)

Solving gives

$$m(x+1) - m(x) = rac{q(1) \cdots q(x)}{p(1) \cdots p(x)} m(1) - \sum_{y=1}^x rac{q(y+1) \cdots q(x)}{p(y) \cdots p(x)}, \quad x \in \mathbb{N}_+$$
 (16.13.26)

Next,  $m(x) = \sum_{y=0}^{x-1} [m(y+1) - m(y)]~~ ext{for}~x \in \mathbb{N}$  which gives

$$m(x) = m(1) \sum_{y=0}^{x-1} \frac{q(1)\cdots q(y)}{p(1)\cdots p(y)} - \sum_{y=0}^{x-1} \sum_{z=1}^{y} \frac{q(z+1)\cdots q(y)}{p(z)\cdots p(y)}, \quad x \in \mathbb{N}$$
(16.13.27)

Finally, m(1) is given as in the first proof. The expression for m(x) is different, but equivalent, of course.

Next we will consider a birth-death chain on a finite integer interval with both endpoints absorbing. Our interest is in the probability of absorption in one endpoint rather than the other, and in the mean time to absorption. Thus suppose that  $n \in \mathbb{N}_+$  and that  $\mathbf{X} = (X_0, X_1, X_2, ...)$  is a birth-death chain on  $\mathbb{N}_n = \{0, 1, ..., n\}$  with r(0) = r(n) = 1 and with p(x) > 0 and q(x) > 0 for  $x \in \{1, 2, ..., n-1\}$ . So the endpoints 0 and n are absorbing, and all other states lead to each other and to the endpoints. Let  $N = \min\{n \in \mathbb{N} : X_n \in \{0, n\}\}$ , the time until absorption, and for  $x \in S$  let  $v_n(x) = \mathbb{P}(X_N = 0 \mid X_0 = x)$  and  $m_n(x) = \mathbb{E}(N \mid X_0 = x)$ . The definitions make sense since N is finite with probability 1.

The absorption probability function for state 0 is given by

$$v_n(x) = rac{1}{A_n} \sum_{i=x}^{n-1} rac{q(1)\cdots q(i)}{p(1)\cdots p(i)} ext{ for } x \in \mathbb{N}_n ext{ where } A_n = \sum_{i=0}^{n-1} rac{q(1)\cdots q(i)}{p(1)\cdots p(i)} ext{ (16.13.28)}$$

Proof

Conditioning and using the Markov property,  $v_n$  satisfies the second-order linear difference equation

$$v_n(x) = p(x)v_n(x+1) + q(x)v_n(x-1) + r(x)v_n(x), \quad x \in \{1, 2, \dots, n-1\}$$
 (16.13.29)

with boundary conditions  $v_n(0) = 1$ ,  $v_n(n) = 0$ . As we have seen before, the difference equation can be rewritten as

$$v_n(x+1)-v_n(x)=rac{p(x)}{q(x)}[v_n(x)-v_n(x-1)], \quad x\in\{1,2,\ldots,n-2\}$$
(16.13.30)

Solving and applying the boundary conditions gives the result.

Note that  $A_n \to A$  as  $n \to \infty$  where A is the constant above for the absorption probability at 0 with the infinite state space  $\mathbb{N}$ . If  $A < \infty$  then  $v_n(x) \to v(x)$  as  $n \to \infty$  for  $x \in \mathbb{N}$ .

The mean absorption time is given by

$$m_n(x) = m_n(1) \sum_{y=0}^{x-1} rac{q(1)\cdots q(y)}{p(1)\cdots p(y)} - \sum_{y=0}^{x-1} \sum_{z=1}^y rac{q(z+1)\cdots q(y)}{p(z)\cdots p(y)}, \quad x \in \mathbb{N}_n$$
 (16.13.31)

where, with  $A_n$  as in the previous theorem,

$$m_n(1) = \frac{1}{A_n} \sum_{y=1}^{n-1} \sum_{z=1}^y \frac{q(z+1)\cdots q(y)}{p(z)\cdots p(y)}$$
(16.13.32)

Proof

The probabilistic proof above with state space  $\mathbb{N}$  and 0 absorbing does not work here, but the first part of the analytic proof does. So,

$$m_n(x) = m_n(1) \sum_{y=0}^{x-1} rac{q(1)\cdots q(y)}{p(1)\cdots p(y)} - \sum_{y=0}^{x-1} \sum_{z=1}^y rac{q(z+1)\cdots q(y)}{p(z)\cdots p(y)}, \quad x \in \{1,2,\ldots,n\}$$
(16.13.33)

Substituting x = n and applying the boundary condition  $m_n(n) = 0$ , gives the result for  $m_n(1)$  in the theorem.

#### Time Reversal

Our next discussion is on the time reversal of a birth-death chain. Essentially, every recurrent birth-death chain is reversible.

Suppose that  $X = (X_0, X_1, X_2, ...)$  is an irreducible, recurrent birth-death chain on an integer interval *S*. Then **X** is reversible.

Proof

We need to show that the Kolmogorov cycle condition is satisfied. That is, for every sequence of states  $(x_0, x_1, x_2, ..., x_n)$  with  $x_0 = x_n$ ,

$$P(x_0, x_1)P(x_1, x_2) \cdots P(x_{n-1}, x_n) = P(x_n, x_{n-1})P(x_{n-1}, x_{n-2}) \cdots P(x_1, x_0)$$
(16.13.34)

We can restrict our attention to sequences where  $x_{i+1} \in \{x_i, x_i - 1, x_i + 1\}$  for each  $i \in \{1, 2, ..., n\}$ . For such sequences, the cycle condition is trivially satisfied.

If *S* is finite and the chain X is irreducible, then of course X is recurrent (in fact positive recurrent), so by the previous result, X is reversible. In the case  $S = \mathbb{N}$ , we can use the invariant function above to show directly that the chain is reversible.

Suppose that  $X = (X_0, X_1, X_2, ...)$  is a birth-death chain on  $\mathbb{N}$  with p(x) > 0 for  $x \in \mathbb{N}$  and q(x) > 0 for  $x \in \mathbb{N}_+$ . Then X is reversible.

Proof

With the function g defined above, it suffices to show the reversibility condition g(x)P(x, y) = g(y)P(y, x) for all  $x, y \in \mathbb{N}$ . It then follows that g is invariant for X and that X is reversible with respect to g. But since g is the only positive invariant function for X, up to multiplication by positive constants, we can omit the qualifying phrase "with respect to g". For  $x \in \mathbb{N}$  and y = x + 1 we have

$$g(x)P(x,y) = g(y)P(y,x) = rac{p(0)\cdots p(x)}{q(1)\cdots q(x)}$$
(16.13.35)

For  $x \in \mathbb{N}_+$  and y = x - 1~ we have

$$g(x)P(x,y) = g(y)P(y,x) = rac{p(0)\cdots p(x-1)}{q(1)\cdots q(x-1)}$$
(16.13.36)

In all other cases, the reversibility condition is trivially satisfied.

Thus, in the positive recurrent case, when the variables are given the invariant distribution, the transition matrix P describes the chain forward in time and backwards in time.

# Examples and Special Cases

As always, be sure to try the problems yourself before looking at the solutions.

## Constant Birth and Death Probabilities

Our first examples consider birth-death chains on  $\mathbb{N}$  with constant birth and death probabilities, except at the boundary points. Such chains are often referred to as *random walks*, although that term is used in a variety of different settings. The results are special cases of the general results above, but sometimes direct proofs are illuminating.

Suppose that  $X = (X_0, X_1, X_2, ...)$  is the birth-death chain on  $\mathbb{N}$  with constant birth probability  $p \in (0, \infty)$  on  $\mathbb{N}$  and constant death probability  $q \in (0, \infty)$  on  $\mathbb{N}_+$ , with  $p + q \leq 1$ . Then

- 1.  $oldsymbol{X}$  is transient if q < p
- 2.  $\boldsymbol{X}$  is null recurrent if q = p
- 3. *X* is positive recurrent if q > p, and the invariant distribution is the geometric distribution on  $\mathbb{N}$  with parameter p/q

$$f(x) = \left(1 - rac{p}{q}
ight) \left(rac{p}{q}
ight)^x, \quad x \in \mathbb{N}$$
 (16.13.37)

Next we consider the random walk on  $\mathbb{N}$  with 0 absorbing. As in the discussion of absorption above, v(x) denotes the absorption probability and m(x) the mean time to absorption, starting in state  $x \in \mathbb{N}$ .

Suppose that  $X = (X_0, X_1, ...)$  is the birth-death chain on  $\mathbb{N}$  with constant birth probability  $p \in (0, \infty)$  on  $\mathbb{N}_+$  and constant death probability  $q \in (0, \infty)$  on  $\mathbb{N}_+$ , with  $p + q \leq 1$ . Assume also that r(0) = 1, so that 0 is absorbing.

1. If  $q \geq p$  then v(x) = 1 for all  $x \in \mathbb{N}$ . If q < p then  $v(x) = (q/p)^x$  for  $x \in \mathbb{N}$ .

2. If  $q \leq p$  then  $m(x) = \infty$  for all  $x \in \mathbb{N}_+$ . If q > p then m(x) = x/(q-p) for  $x \in \mathbb{N}$ .

Proof

- 1. This follows from the general result above for the absorption probability.
- 2. This also follows from the general result above for the mean absorption time, but we will give a direct proof using the same ideas. If q < p then  $\mathbb{P}(N = \infty \mid X_0 = x) > 0$  and hence  $m(x) = \infty$  for  $x \in \mathbb{N}_+$ . So suppose that  $q \ge p$  so that  $\mathbb{P}(N < \infty \mid X_0 = x) = 1$  for  $x \in \mathbb{N}$ . Because of the spatial homogeneity, the time required to reach state x 1 starting in state  $x \in \mathbb{N}_+$  has the same distribution as the time required to reach state 0 starting in state 1. By the additivity of expected value, it follows that m(x) = x m(1) for  $x \in \mathbb{N}$ . So it remains for us to compute m(1). Starting in state 1, the chain will be absorbed into state 0 after a random number of intermediate returns to state 1 with absorption. In state 1, the

probability of absorption at the next step is q, so the number of times that the chain is in state 1 before absorption has the geometric distribution on  $\mathbb{N}_+$  with success parameter q. So the mean number of visits is 1/q. In state 1, the number of steps before a return to step 1 without absorption has the same distribution as the return time to state 0, starting in 0, for the recurrent chain considered in the previous exercise. The mean of this distribution is  $\infty$  if q = p and is 1/f(0) if q > p, were f is the invariant distribution. It follows that

$$m(1) = \frac{1}{q} \frac{1}{1 - p/q} = \frac{1}{q - p}$$
(16.13.38)

This chain is essentially the *gambler's ruin chain*. Consider a gambler who bets on a sequence of independent games, where p and q are the probabilities of winning and losing, respectively. The gambler receives one monetary unit when she wins a game and must pay one unit when she loses a game. So  $X_n$  is the gambler's fortune after playing n games.

Next we consider random walks on a finite interval.

Suppose that  $X = (X_0, X_1, ...)$  is the birth-death chain on  $\mathbb{N}_n = \{0, 1, ..., n\}$  with constant birth probability  $p \in (0, \infty)$  on  $\{0, 1, ..., n-1\}$  and constant death probability  $q \in (0, \infty)$  on  $\{1, 2, ..., n\}$ , with  $p + q \le 1$ . Then X is positive recurrent and the invariant probability density function  $f_n$  is given as follows:

1. If  $p \neq q$  then

$$f_n(x) = rac{(p/q)^x(1-p/q)}{1-(p/q)^{n+1}}, \quad x \in \mathbb{N}_n$$
 (16.13.39)

2. If p=q then  $f_n(x)=1/(n+1)$  for  $x\in\mathbb{N}_n.$ 

Note that if p < q then the invariant distribution is a truncated geometric distribution, and  $f_n(x) \to f(x)$  for  $x \in \mathbb{N}$  where f is the invariant probability density function of the birth-death chain on  $\mathbb{N}$  considered above. If p = q, the invariant distribution is uniform on  $\mathbb{N}_n$ , certainly a reasonable result. Next we consider the chain with both endpoints absorbing. As before,  $v_n$  is the function that gives the probability of absorption in state 0, while  $m_n$  is the function that gives the mean time to absorption.

Suppose that  $X = (X_0, X_1, ...)$  is the birth-death chain on  $\mathbb{N}_n = \{0, 1, ..., n\}$  with constant birth probability  $p \in (0, 1)$  and death probability  $q \in (0, \infty)$  on  $\{1, 2, ..., n-1\}$ , where  $p + q \leq 1$ . Assume also that r(0) = r(n) = 1, so that 0 and *n* are absorbing.

1. If  $p \neq q$  then

$$v_n(x) = rac{(q/p)^x - (q/p)^n}{1 - (q/p)^n}, \quad x \in \mathbb{N}_n$$
 (16.13.40)

2. If p = q then  $v_n(x) = 1 - x/n$  for  $x \in \mathbb{N}_n$ 

Note that if q < p then  $v_n(x) \rightarrow v(x)$  as  $n \rightarrow \infty$  for  $x \in \mathbb{N}$ .

Suppose again that  $X = (X_0, X_1, ...)$  is the birth-death chain on  $\mathbb{N}_n = \{0, 1, ..., n\}$  with constant birth probability  $p \in (0, 1)$  and death probability  $q \in (0, \infty)$  on  $\{1, 2, ..., n-1\}$ , where  $p + q \le 1$ . Assume also that r(0) = r(n) = 1, so that 0 and *n* are absorbing.

1. If  $p \neq q$  then

$$m_n(x) = rac{n}{p-q} rac{1-(q/p)^x}{1-(q/p)^n} + rac{x}{q-p}, \quad x \in \mathbb{N}_n$$
 (16.13.41)

2. If p = q then

$$m_n(x)=rac{1}{2p}x(n-x),\quad x\in\mathbb{N}_n$$
 (16.13.42)

# Special Birth-Death Chains

Some of the random processes that we have studied previously are birth-death Markov chains.

Describe each of the following as a birth-death chain.

- 1. The Ehrenfest chain.
- 2. The modified Ehrenfest chain.
- 3. The Bernoulli-Laplace chain
- 4. The simple random walk on  $\mathbb{Z}$ .

Answer

- 1. The Ehrenfest chain with parameter  $m \in \mathbb{N}_+$  is a birth death chain on  $S = \{0, 1, \dots, m\}$  with  $q(x) = \frac{x}{m}$  and  $p(x) = \frac{m-x}{m}$  for  $x \in S$ .
- 2. The modified Ehrenfest chain with parameter  $m \in \mathbb{N}_+$  is a birth death chain on  $S = \{0, 1, \dots, m\}$  with  $q(x) = \frac{x}{2m}$ ,  $r(x) = \frac{1}{2}$ , and  $p(x) = \frac{m-x}{2m}$  for  $x \in S$ .
- 3. The Bernoulli-Laplace chain with parameters  $j, k, r \in \mathbb{N}_+$  with r < j+k is a birth-death chain on  $S = \{\max\{0, r-j\}, \dots, \min\{k, r\}\}$  with  $q(x) = \frac{(j-r+x)x}{jk}$ ,  $r(x) = \frac{(r-x)x+(j-r+x)(k-x)}{jk}$ , and  $p(x) = \frac{(r-x)(k-x)}{jk}$  for  $x \in S$ .
- 4. The simple random walk on  $\mathbb Z$  with parameter  $p \in (0, 1)$  is a birth-death chain on  $\mathbb Z$  with p(x) = p and q(x) = 1 p for  $x \in \mathbb Z$ .

#### Other Examples

Consider the birth-death process on  $\mathbb N$  with  $p(x)=rac{1}{x+1}$  , q(x)=1-p(x) , and r(x)=0 for  $x\in S.$ 

- 1. Find the invariant function g.
- 2. Classify the chain.

Answer

1. Note that 
$$p(0)\cdots p(x-1)=rac{1}{x!}$$
 and  $q(1)\cdots q(x)=rac{1}{x+1}=p(x)$  for  $x\in\mathbb{N}$ . Hence  $g(x)=rac{x+1}{x!}$ .

2. Note that

$$\sum_{x=0}^{\infty} g(x) = \sum_{x=1}^{\infty} \frac{1}{(x-1)!} + \sum_{x=0}^{\infty} \frac{1}{x!} = 2e$$
(16.13.43)

So the chain is positive recurrent, with invariant PDF f given by

$$f(x) = e^{-2} \, rac{(x+1)}{x!}, \quad x \in \mathbb{N}$$
 (16.13.44)

Also, the chain is periodic with period 2.

# 16.14: Random Walks on Graphs

# **Basic Theory**

Introduction

Suppose that G = (S, E) is a graph with vertex set S and edge set  $E \subseteq S^2$ . We assume that the graph is *undirected* (perhaps a better term would be *bi-directed*) in the sense that  $(x, y) \in E$  if and only if  $(y, x) \in E$ . The vertex set S is countable, but may be infinite. Let  $N(x) = \{y \in S : (x, y) \in E\}$  denote the set of *neighbors* of a vertex  $x \in S$ , and let d(x) = #[N(x)] denote the *degree* of x. We assume that  $N(x) \neq \emptyset$  for  $x \in S$ , so G has no isolated points.

Suppose now that there is a *conductance* c(x, y) > 0 associated with each edge  $(x, y) \in E$ . The conductance is symmetric in the sense that c(x, y) = c(y, x) for  $(x, y) \in E$ . We extend c to a function on all of  $S \times S$  by defining c(x, y) = 0 for  $(x, y) \notin E$ . Let

$$C(x)=\sum_{y\in S}c(x,y),\quad x\in S$$
 $(16.14.1)$ 

so that C(x) is the total conductance of the edges coming from x. Our main assumption is that  $C(x) < \infty$  for  $x \in S$ . As the terminology suggests, we imagine a fluid of some sort flowing through the edges of the graph, so that the conductance of an edge measures the capacity of the edge in some sense. One of the best interpretation is that the graph is an *electrical network* and the edges are *resistors*. In this interpretation, the conductance of a resistor is the reciprocal of the resistance.

In some applications, specifically the resistor network just mentioned, it's appropriate to impose the additional assumption that G has no loops, so that  $(x, x) \notin E$  for each  $x \in S$ . However, that assumption is not mathematically necessary for the Markov chains that we will consider in this section.

The discrete-time Markov chain  $X = (X_0, X_1, X_2, ...)$  with state space *S* and transition probability matrix *P* given by

$$P(x,y) = rac{c(x,y)}{C(x)}, \quad (x,y) \in S^2$$
 (16.14.2)

is called a *random walk* on the graph G.

Justification

First,  $P(x,y) \geq 0$  for  $x, y \in S.$  Next, by definition of C,

$$\sum_{y \in S} P(x, y) = \sum_{y \in S} \frac{c(x, y)}{C(x)} = \frac{C(x)}{C(x)} = 1, \quad x \in S$$
(16.14.3)

sp *P* is a valid transition matrix on *S*. Also, P(x, y) > 0 if and only if c(x, y) > 0 if and only if  $(x, y) \in E$ , so the state graph of *X* is *G*, the graph we started with.

This chain governs a particle moving along the vertices of *G*. If the particle is at vertex  $x \in S$  at a given time, then the particle will be at a neighbor of *x* at the next time; the neighbor is chosen randomly, in proportion to the conductance. In the setting of an electrical network, it is natural to interpret the particle as an electron. Note that multiplying the conductance function *c* by a positive constant has no effect on the associated random walk.

Suppose that  $d(x) < \infty$  for each  $x \in S$  and that *c* is constant on the edges. Then

1. 
$$C(x) = cd(x)$$
 for every  $x \in S$ 

2. The transition matrix P is given by  $P(x,y) = \frac{1}{d(x)}$  for  $x \in S$  and  $y \in N(x)$ , and P(x,y) = 0 otherwise.

The discrete-time Markov chain  $\boldsymbol{X}$  is the *symmetric random walk* on G.

## Proof

$$egin{aligned} 1.\ C(x) = \sum_{y \in N(x)} c(x,y) = c \# [N(x)] = c d(x) & ext{for } x \in S \,. \ 2.\ P(x,y) = c(x,y) / C(x) = c / c d(x) = 1 / d(x) & ext{for } x \in S \, ext{ and } y \in N(x) \end{aligned}$$

 $\odot$ 

Thus, for the symmetric random walk, if the state is  $x \in S$  at a given time, then the next state is equally likely to be any of the neighbors of x. The assumption that each vertex has finite degree means that the graph G is *locally finite*.

Let  $\boldsymbol{X}$  be a random walk on a graph G.

1. If G is connected then  $\boldsymbol{X}$  is irreducible.

2. If *G* is not connected then the equivalence classes of X are the *components* of *G* (the maximal connected subsets of *S*).

Proof

1. Recall that there is a path of length  $n \in \mathbb{N}_+$  between distinct states  $x, y \in S$  in the state graph of X if and only if

 $P^n(x,y) > 0$ . If G is connected, there is a path between each pair of distinct vertices and hence the chain X is irreducible.

2. This follows from (a).

So as usual, we will usually assume that G is connected, for otherwise we could simply restrict our attention to a component of G. In the case that G has no loops (again, an important special case because of applications), it's easy to characterize the periodicity of the chain. For the theorem that follows, recall that G is *bipartite* if the vertex set S can be partitioned into nonempty, disjoint sets A and B (the parts) such that every edge in E has one endpoint in A and one endpoint in B.

Suppose that X is a random walk on a connected graph G with no loops. Then X is either aperiodic or has period 2. Moreover, X has period 2 if and only if G is bipartite, in which case the parts are the cyclic classes of X.

# Proof

First note that since *G* is connected, the chain *X* is irreducible, and so all states have the same period. If  $(x, y) \in E$  then  $(y, x) \in E$  also, so returns to  $x \in S$ , starting at *x* can always occur at even positive integers. If *G* is bipartite, then returns to *x* starting at *x* can clearly only occur at even positive integers, so the period is 2. Conversely, if *G* is not bipartite then *G* has a cycle of odd length *k*. If *x* is a vertex on the cycle, then returns to *x*, starting at *x*, can occur in 2 steps or in *k* steps, so the period of *x* is 1.

# Positive Recurrence and Invariant Distributions

Suppose again that X is a random walk on a graph G, and assume that G is connected so that X is irreducible.

The function C is invariant for P. The random walk X is positive recurrent if and only if

$$K = \sum_{x \in S} C(x) = \sum_{(x,y) \in S^2} c(x,y) < \infty$$
 (16.14.4)

in which case the invariant probability density function f is given by f(x) = C(x)/K for  $x \in S$ .

Proof

For  $y\in S$  ,

$$(CP)(y) = \sum_{x \in S} C(x)P(x,y) = \sum_{x \in N(y)} C(x)\frac{c(x,y)}{C(x)} = \sum_{x \in N(y)} c(x,y) = C(y)$$
(16.14.5)

so C is invariant for P. The other results follow from the general theory.

Note that K is the total conductance over all edges in G. In particular, of course, if S is finite then X is positive recurrent, with f as the invariant probability density function. For the symmetric random walk, this is the only way that positive recurrence can occur:

The symmetric random walk on G is positive recurrent if and only if the set of vertices S is finite, in which case the invariant probability density function f is given by

$$f(x) = rac{d(x)}{2m}, \quad x \in S$$
 (16.14.6)

where d is the degree function and where m is the number of undirected edges.

Proof

If we take the conductance function to be the constant 1 on the edges, then C(x) = d(x) and K = 2m.

On the other hand, when *S* is infinite, the classification of *X* as recurrent or transient is complicated. We will consider an interesting special case below, the symmetric random walk on  $\mathbb{Z}^k$ .

#### Reversibility

Essentially, all reversible Markov chains can be interpreted as random walks on graphs. This fact is one of the reasons for studying such walks.

If  $\boldsymbol{X}$  is a random walk on a connected graph G, then  $\boldsymbol{X}$  is reversible with respect to C.

Proof

Since the graph is connected,  $\boldsymbol{X}$  is irreducible. The crucial observation is that

$$C(x)P(x,y) = C(y)P(y,x), \quad (x,y) \in S^2$$
  
(16.14.7)

If  $(x, y) \in E$  the left side is c(x, y) and the right side is c(y, x). If  $(x, y) \notin E$ , both sides are 0. It then follows from the general theory that *C* is invariant for **X** and that **X** is reversible with respect to *C*.

Of course, if X is recurrent, then C is the only positive invariant function, up to multiplication by positive constants, and so X is simply reversible.

Conversely, suppose that X is an irreducible Markov chain on S with transition matrix P and positive invariant function g. If X is reversible with respect to g then X is the random walk on the state graph with conductance function c given by c(x, y) = g(x)P(x, y) for  $(x, y) \in S^2$ .

Proof

Since X is reversible with respect to g, g and P satisfy g(x)P(x, y) = g(y)P(y, x) for every  $(x, y) \in S^2$ . Note that the state graph G of X is bi-directed since P(x, y) > 0 if and only if P(y, x) > 0, and that the function c given in the theorem is symmetric, so that c(x, y) = c(y, x) for all  $(x, y) \in S^2$ . Finally, note that

$$C(x) = \sum_{y \in S} c(x, y) = \sum_{y \in S} g(x) P(x, y) = g(x), \quad x \in S$$
(16.14.8)

so that P(x,y)=c(x,y)ig/C(x) for  $(x,y)\in S^2$  , as required.

Again, in the important special case that X is recurrent, there exists a positive invariant function g that is unique up to multiplication by positive constants. In this case the theorem states that an irreducible, recurrent, reversible chain is a random walk on the state graph.

# **Examples and Applications**

## The Wheatstone Bridge Graph

The graph below is called the *Wheatstone bridge* in honor of Charles Wheatstone.

Figure 16.14.1: The Wheatstone bridge network, with conductance values in red

In this subsection, let X be the random walk on the Wheatstone bridge above, with the given conductance values.

For the random walk X,

1. Explicitly give the transition probability matrix *P*.

2. Given  $X_0 = a$ , find the probability density function of  $X_2$ .

Answer

For the matrix and vector below, we use the ordered state space S = (a, b, c, d).

$$1. P = \begin{bmatrix} 0 & \frac{1}{2} & 0 & \frac{1}{2} \\ \frac{1}{4} & 0 & \frac{1}{4} & \frac{1}{2} \\ 0 & \frac{1}{3} & 0 & \frac{2}{3} \\ \frac{1}{5} & \frac{2}{5} & \frac{2}{5} & 0 \end{bmatrix}$$
$$2. f_2 = \left(\frac{9}{40}, \frac{1}{5}, \frac{13}{40}, \frac{1}{4}\right)$$

For the random walk X,

1. Show that  $\boldsymbol{X}$  is aperiodic.

2. Find the invariant probability density function.

3. Find the mean return time to each state.

4. Find  $\lim_{n\to\infty} P^n$ .

Answer

For the matrix and vectors below, we use the ordered state space (a, b, c, d).

1. The chain is aperiodic since the graph is not bipartite. (Note that the graph has triangles.)

2. 
$$f = \left(\frac{1}{7}, \frac{2}{7}, \frac{3}{14}, \frac{5}{14}\right)$$
  
3.  $\mu = \left(7, \frac{7}{2}, \frac{14}{3}, \frac{14}{5}\right)$   
4.  $P^n \rightarrow \begin{bmatrix} \frac{1}{7} & \frac{2}{7}, \frac{3}{14}, \frac{5}{14}\\ \frac{1}{7} & \frac{2}{7}, \frac{3}{14}, \frac{5}{14}\\ \frac{1}{7} & \frac{2}{7}, \frac{3}{14}, \frac{5}{14}\\ \frac{1}{7} & \frac{2}{7}, \frac{3}{14}, \frac{5}{14} \end{bmatrix}$  as  $n \rightarrow \infty$ 

# The Cube Graph

The graph below is the 3-dimensional *cube graph*. The vertices are bit strings of length 3, and two vertices are connected by an edge if and only if the bit strings differ by a single bit.

Figure 16.14.2: The cube graph with conductance values in red

In this subsection, let  $\boldsymbol{X}$  denote the random walk on the cube graph above, with the given conductance values.

For the random walk X,

- 1. Explicitly give the transition probability matrix *P*.
- 2. Suppose that the initial distribution is the uniform distribution on  $\{000, 001, 101, 100\}$ Find the probability density function of  $X_2$ .

Answer

For the matrix and vector below, we use the ordered state space S = (000, 001, 101, 110, 010, 011, 111, 101)

	0	$\frac{1}{4}$	0	$\frac{1}{4}$	$\frac{1}{2}$	0	0	0
1. <i>P</i> =	$\frac{1}{4}$	0	$\frac{1}{4}$	0	0	$\frac{1}{2}$	0	0
	0	$\frac{1}{4}$	0	$\frac{1}{4}$	0	0	$\frac{1}{2}$	0
	$\frac{1}{4}$	0	$\frac{1}{4}$	0	0	0	0	$\frac{1}{2}$
	$\frac{1}{4}$	0	0	0	0	$\frac{3}{9}$	0	$\frac{3}{8}$
	0	$\frac{1}{4}$	0	0	$\frac{3}{8}$	0	$\frac{3}{8}$	0
	0	0	$\frac{1}{4}$	0	0	$\frac{3}{8}$	0	$\frac{3}{8}$
	0	0	0	$\frac{1}{4}$	$\frac{3}{8}$	0	$\frac{3}{8}$	0
2. $f_2 =$	$\left(\frac{3}{32}\right)$	$\frac{3}{32}$ ,	$\frac{3}{32}$ ,	$\frac{3}{32}$ ,	$\frac{5}{32}, \frac{5}{32}$	$\frac{5}{2}, \frac{5}{32}$	$\frac{5}{32}$	)

For the random walk  $\boldsymbol{X}$ ,

- 1. Show that the chain has period 2 and find the cyclic classes.
- 2. Find the invariant probability density function.
- 3. Find the mean return time to each state.

4. Find  $\lim_{n\to\infty} P^{2n}$ .

5. Find  $\lim_{n\to\infty} P^{2n+1}$ .

Answer

For the matrix and vector below, we use the ordered state space S = (000, 001, 101, 110, 010, 011, 111, 101)

1. The chain has period 2 since the graph is bipartite. The cyclic classes are {000, 011, 110, 101(bit strings with an even number of 1's) and {010, 001, 100, 111(bit strings with an odd number of 1's).

$$2. f = \left(\frac{1}{12}, \frac{1}{12}, \frac{1}{12}, \frac{1}{12}, \frac{1}{6}, \frac{1}{6}, \frac{1}{6}, \frac{1}{6}\right)$$

$$3. \mu = (12, 12, 12, 12, 6, 6, 6, 6)$$

$$4. P^{2n} \rightarrow \begin{bmatrix} \frac{1}{6} & 0 & \frac{1}{6} & 0 & 0 & \frac{1}{3} & 0 & \frac{1}{3} \\ 0 & \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0 & 0 & \frac{1}{6} & \frac{1}{3} & 0 & \frac{1}{3} & 0 \\ \frac{1}{6} & 0$$

# **Special Models**

Recall that the basic Ehrenfest chain with  $m \in \mathbb{N}_+$  balls is reversible. Interpreting the chain as a random walk on a graph, sketch the graph and find a conductance function.

## Answer

The state graph *G* of the basic Ehrenfest chain with *m* balls is the path from 0 to *m* with no loops. A conductance function *c* is  $c(x, x+1) = \binom{m-1}{x}$  for  $x \in \{0, 1, ..., m-1\}$ .

Recall that the modified Ehrenfest chain with  $m \in \mathbb{N}_+$  balls is reversible. Interpreting the chain as a random walk on a graph, sketch the graph and find a conductance function.

## Answer

The state graph G of the modified Ehrenfest chain with m balls is the path from 0 to m with loops. A conductance function c is  $c(x, x+1) = \frac{1}{2} \binom{m-1}{x}$  for  $x \in \{0, 1, \dots, m-1\}$  and  $c(x, x) = \frac{1}{2} \binom{m}{x}$  for  $x \in \{0, 1, \dots, m\}$ .

Recall that the Bernoulli-Laplace chain with  $j \in \mathbb{N}_+$  balls in urn 0,  $k \in \mathbb{N}_+$  balls in urn 1, and with  $r \in \{0, \ldots, j+k\}$  of the balls red, is reversible. Interpreting the chain as a random walk on a graph, sketch the graph and find a conductance function. Simplify the conductance function in the special case that j = k = r.

#### Answer

The state graph *G* of the Bernoulli-Lapace chain with *j* balls in urn 0, *k* balls in urn 1, and with *r* of the balls red, is the path from  $\max\{0, r-j\}$  to  $\min\{k, r\}$  with loops. A conductance function *c* is given by

$$egin{aligned} c(x,x+1) &= inom{r}{x} inom{j+k-r}{k-x} (r-x)(k-x), & x \in \{\max\{0,r-j\},\dots,\min\{k,r\}-1\} \ c(x,x) &= inom{r}{x} inom{j+k-r}{k-x} [(r-x)x+(j-r+x)(k-x)], & x \in \{\max\{0,r-j\},\dots,\min\{k,r\}\} \end{aligned}$$

In the special case that j = k = r, a conductance function is

C

$$egin{aligned} & k(x,x+1) \ &= inom{k}{x}inom{k}{k-x}(k-x)^2, & x\in\{0,\ldots,k-1\} \ & c(x,x) \ &= inom{k}{x}inom{k}{k-x}2x(k-x), & x\in\{0,\ldots,k\} \end{aligned}$$

## Random Walks on $\mathbb{Z}$

Random walks on integer lattices are particularly interesting because of their classification as transient or recurrent. We consider the one-dimensional case in this subsection, and the higher dimensional case in the next subsection.

Let  $X = (X_0, X_1, X_2, ...)$  be the discrete-time Markov chain with state space  $\mathbb{Z}$  and transition probability matrix P given by

$$P(x,x+1) = p, \ P(x,x-1) = 1-p, \quad x \in \mathbb{Z}$$
 (16.14.9)

where  $p \in (0, 1)$ . The chain X is called the *simple random walk* on  $\mathbb{Z}$  with parameter p.

The term *simple* is used because the transition probabilities starting in state  $x \in \mathbb{Z}$  do not depend on x. Thus the chain is *spatially* as well as *temporally* homogeneous. In the special case  $p = \frac{1}{2}$ , the chain X is the *simple symmetric random walk* on  $\mathbb{Z}$ . Basic properties of the simple random walk on  $\mathbb{Z}$ , and in particular, the simple symmetric random walk were studied in the chapter on Bernoulli Trials. Of course, the state graph G of X has vertex set  $\mathbb{Z}$ , and the neighbors of  $x \in \mathbb{Z}$  are x + 1 and x - 1. It's not immediately clear that X is a random walk on G associated with a conductance function, which after all, is the topic of this section. But that fact and more follow from the next result.

Let *g* be the function on  $\mathbb{Z}$  defined by

$$g(x)=\left(rac{p}{1-p}
ight)^x, \quad x\in\mathbb{Z}$$
 (16.14.10)

#### Then

1. g(x)P(x,y) = g(y)P(y,x) for all  $(x,y) \in \mathbb{Z}^2$ 

2. g is invariant for  $\boldsymbol{X}$ 

3.  $\boldsymbol{X}$  is reversible with respect to g

4. **X** is the random walk on  $\mathbb{Z}$  with conductance function c given by  $c(x, x + 1) = p^{x+1}/(1-p)^x$  for  $x \in \mathbb{Z}$ .

## Proof

1. For  $x\in\mathbb{Z}$  , we only need to consider  $y=x\pm 1$  .

$$egin{aligned} g(x)P(x,x-1) &= rac{p^x}{(1-p)^{x-1}} = g(x-1)P(x-1,x) \ g(x)P(x,x+1) &= rac{p^{x+1}}{(1-p)^x} = g(x+1)P(x+1,x) \end{aligned}$$

2. This follows from (a) and the general theory.

3. This follows from (a) and (b) and the general theory.

4. From the result above, X is the random walk on G associated with the conductance function c given by c(x, y) = g(x)P(x, y). By symmetry, it suffices to consider the edge (x, x + 1), and in this case, c is given in the second displayed equation above.

In particular, the simple symmetric random walk is the symmetric random walk on G.

The chain  $\boldsymbol{X}$  is irreducible and periodic with period 2. Moreover

$$P^{2n}(0,0) = {2n \choose n} p^n (1-p)^n, \quad n \in \mathbb{N}$$
 (16.14.11)

Proof

The chain is irreducible since G is connected. The chain is periodic since G has no loops and is bipartite, with the parts being the odd and even integers. Finally, note that starting in state 0, the chain returns to 0 at time 2n if and only if there are n steps to the right and n steps to the left.

Classification of the simple random walk on  $\mathbb{Z}$ .

1. If  $p \neq \frac{1}{2}$  then  $\boldsymbol{X}$  is transient. 2. If  $p = \frac{1}{2}$  then  $\boldsymbol{X}$  is null recurrent.

Proof

From the previous result and Stirling's approximation,

$$P^{2n}(0,0) pprox rac{[4p(1-p)]^n}{\sqrt{\pi \, n}} ext{ as } n o \infty ext{ (16.14.12)}$$

Let  $R(x, y) = \sum_{n=0}^{\infty} P^n(x, y)$  for  $(x, y) \in \mathbb{Z}^2$ , so that R is the potential matrix. Recall that R(x, y) is the expected number of visits to y starting in x for  $(x, y) \in \mathbb{Z}^2$ . If  $p \neq \frac{1}{2}$  then  $R(0, 0) < \infty$  and hence  $\boldsymbol{X}$  is transient. If  $p = \frac{1}{2}$  then  $R(0, 0) = \infty$  and hence  $\boldsymbol{X}$  is recurrent. In this case  $\boldsymbol{X}$  must be null recurrent from our general results above, since the vertex set is infinite.

So for the one-dimensional lattice  $\mathbb{Z}$ , the random walk X is transient in the non-symmetric case, and null recurrent in the symmetric case. Let's return to the invariant functions of X

Consider again the random walk X on  $\mathbb{Z}$  with parameter  $p \in (0, 1)$ . The constant function **1** on  $\mathbb{Z}$  and the function g given by

$$g(x) = \left(rac{p}{1-p}
ight)^x, \quad x \in \mathbb{Z}$$
 (16.14.13)

are invariant for X. All other invariant functions are linear combinations of these two functions. Proof

The condition for *h* to be invariant, hP = h, leads to the following linear, second order difference equation:

$$(1-p)h(y+1) - h(y) + (1+p)h(y-1), \quad y \in \mathbb{Z}$$
 (16.14.14)

The characteristic equation is  $(1-p)r^2 - r + (1+p) = 0$  which has roots r = 1 and r = p/(1-p). The solutions corresponding to the roots are **1** and *g*, respectively. Hence the result follows from the general theory of linear difference equations.

Note that when  $p = \frac{1}{2}$ , the constant function **1** is the only positive invariant function, up to multiplication by positive constants. But we know this has to be the case since the chain is recurrent when  $p = \frac{1}{2}$ . Moreover, the chain is reversible. In the non-symmetric case, when  $p \neq \frac{1}{2}$ , we have an example of a transient chain which nonetheless has non-trivial invariant functions—in fact a two dimensional space of such functions. Also, X is reversible with respect to g, as shown above, but the reversal of X with respect to **1** is the chain with transition matrix Q given by Q(x, y) = P(y, x) for  $(x, y) \in \mathbb{Z}^2$ . This chain is just the simple random walk on Z with parameter 1 - p. So the non-symmetric simple random walk is an example of a transient chain that is reversible with respect to one invariant measure but not with respect to another invariant measure.

## Random walks on $\mathbb{Z}^k$

More generally, we now consider  $\mathbb{Z}^k$ , where  $k \in \mathbb{N}_+$ . For  $i \in \{1, 2, ..., k\}$ , let  $u_i \in \mathbb{Z}^k$  denote the unit vector with 1 in position i and 0 elsewhere. The k-dimensional integer lattice G has vertex set  $Z^k$ , and the neighbors of  $\boldsymbol{x} \in \mathbb{Z}^k$  are  $\boldsymbol{x} \pm \boldsymbol{u}_i$  for  $i \in \{1, 2, ..., k\}$ . So in particular, each vertex has 2k neighbors.

Let 
$$\mathscr{X} = (\mathbf{X}_1, \mathbf{X}_2, ...)$$
 be the Markov chain on  $\mathbb{Z}^k$  with transition probability matrix  $P$  given by  
 $P(\mathbf{x}, \mathbf{x} + \mathbf{u}_i) = p_i, \ P(\mathbf{x}, \mathbf{x} - \mathbf{u}_i) = q_i; \quad \mathbf{x} \in \mathbb{Z}^k, \ i \in \{1, 2, ..., k\}$  (16.14.15)  
where  $p_i > 0, \ q_i > 0$  for  $i \in \{1, 2, ..., k\}$  and  $\sum_{i=1}^k (p_i + q_i) = 1$ . The chain  $\mathscr{X}$  is the simple random walk on  $\mathbb{Z}^k$  with

where  $p_i > 0$ ,  $q_i > 0$  for  $i \in \{1, 2, ..., k\}$  and  $\sum_{i=1}^{\kappa} (p_i + q_i) = 1$ . The chain  $\mathscr{X}$  is the simple random walk on  $\mathbb{Z}^k$  with parameters  $\boldsymbol{p} = (p_1, p_2, ..., p_k)$  and  $\boldsymbol{q} = (q_1, q_2, ..., q_k)$ .

Again, the term *simple* means that the transition probabilities starting at  $\boldsymbol{x} \in \mathbb{Z}^k$  do not depend on  $\boldsymbol{x}$ , so that the chain is spatially homogeneous as well as temporally homogeneous. In the special case that  $p_i = q_i = \frac{1}{2k}$  for  $i \in \{1, 2, ..., k\}$ ,  $\mathscr{X}$  is the *simple symmetric random walk on*  $Z^k$ . The following theorem is the natural generalization of the result above for the one-dimensional case.

Define the function  $g: \mathbb{Z}^k \to (0,\infty)$  by

$$g(x_1, x_2, \dots, x_k) = \prod_{i=1}^k \left(\frac{p_i}{q_i}\right)^{x_i}, \quad (x_1, x_2, \dots, x_k) \in \mathbb{Z}^k$$
(16.14.16)

Then

1.  $g(\boldsymbol{x})P(\boldsymbol{x},\boldsymbol{y}) = g(\boldsymbol{y})P(\boldsymbol{y},\boldsymbol{x})$  for all  $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{Z}^k$ 

2. *g* is invariant for  $\mathscr{X}$ .

3.  $\mathscr{X}$  is reversible with respect to *g*.

4.  $\mathscr{X}$  is the random walk on *G* with conductance function *c* given by  $c(\boldsymbol{x}, \boldsymbol{y}) = g(\boldsymbol{x})P(\boldsymbol{x}, \boldsymbol{y})$  for  $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{Z}^k$ .

Proof

1. For  $\boldsymbol{x} = (x_1, x_2, \dots, x_k) \in Z^k$ , the only cases of interest are  $\boldsymbol{y} = \boldsymbol{x} \pm \boldsymbol{u}_i$  for  $i \in \{1, 2, \dots, k\}$ , since in all other cases, the left and right sides are 0. But

$$egin{aligned} g(oldsymbol{x})P(oldsymbol{x},oldsymbol{x}+oldsymbol{u}_i) &= \prod_{j
eq i} \left(rac{p_j}{q_j}
ight)^{x_j} \cdot rac{p_i^{x_i+1}}{q_i^{x_i}} = g(oldsymbol{x}+oldsymbol{u}_i)P(oldsymbol{x}+oldsymbol{u}_i,oldsymbol{x}) \ g(oldsymbol{x})P(oldsymbol{x},oldsymbol{x}-oldsymbol{u}_i) &= \prod_{j
eq i} \left(rac{p_j}{q_j}
ight)^{x_j} \cdot rac{p_i^{x_i}}{q_i^{x_i-1}} = g(oldsymbol{x}-oldsymbol{u}_i)P(oldsymbol{x}+oldsymbol{u}_i,oldsymbol{x}) \end{aligned}$$

2. This follows from (a).

3. This follows from (a) and (b).

## 4. This also follows from the general result above.

It terms of recurrence and transience, it would certainly seem that the larger the dimension k, the less likely the chain is to be recurrent. That's generally true:

Classification of the simple random walk on  $\mathbb{Z}^k$ .

1. For  $k \in \{1, 2\}$ ,  $\mathscr{X}$  is null recurrent in the symmetric case and transient for all other values of the parameters.

2. For  $k \in \{3, 4, \ldots\}$ ,  $\mathscr{X}$  is transient for all values of the parameters.

Proof sketch

For certain of the non-symmetric cases, we can use the result for dimension 1. Suppose  $i \in \{1, 2, ..., k\}$  with  $p_i \neq q_i$ . If we consider the times when coordinate i of the random walk  $\mathscr{X}$  changes, we have an embedded one-dimensional random walk with parameter  $p = p_i / (p_i + q_i)$  (the probability of a step in the positive direction). Since  $p \neq \frac{1}{2}$ , this embedded random walk is transient and so will fail to return to 0, starting at 0, with positive probability. But if this embedded random walk fails to return to 0, starting at 0, then the parent random walk  $\mathscr{X}$  fails to return to 0 starting at 0. Hence  $\mathscr{X}$  is transient.

For the symmetric case, the general proof is similar in to the proof for dimension 1, but the details are considerably more complex. A return to 0 can occur only at even times and

$$P^{2n}(\mathbf{0},\mathbf{0}) \approx rac{C_k}{n^{k/2}} ext{ as } n \to \infty ext{ where } C_k = rac{k^{k/2}}{\pi^{k/2} 2^{k-1}}$$
 (16.14.17)

Thus for the potential matrix R we have  $R(\mathbf{0}, \mathbf{0}) = \infty$  and the chain is recurrent if  $k \in \{1, 2\}$  while  $R(\mathbf{0}, \mathbf{0}) < \infty$  and the chain is transient if  $k \in \{3, 4, \ldots\}$ .

So for the simple, symmetric random walk on the integer lattice  $\mathbb{Z}^k$ , we have the following interesting *dimensional phase shift*: the chain is null recurrent in dimensions 1 and 2 and transient in dimensions 3 or more.

Let's return to the positive invariant functions for  $\mathscr{X}$ . Again, the results generalize those for the one-dimensional case.

For 
$$J \subseteq \{1, 2..., k\}$$
, define  $g_J$  on  $\mathbb{Z}^k$  by  
 $g_J(x_1, x_2, ..., x_k) = \prod_{j \in J} \left(\frac{p_j}{q_j}\right)^{x_j}, \quad (x_1, x_2, ..., x_k) \in \mathbb{Z}^k$ 

$$(16.14.18)$$

Let  $\mathscr{X}_J$  denote the simple random walk on  $\mathbb{Z}^k$  with transition matrix  $P_J$ , corresponding to the parameter vectors  $\boldsymbol{p}^J$  and  $\boldsymbol{q}^J$ , where  $p_j^J = p_j$ ,  $q_j^J = q_j$  for  $j \in J$ , and  $p_j^J = q_j$ ,  $q_j^J = p_j$  for  $j \notin J$ . Then

1.  $g_J(oldsymbol{x})P(oldsymbol{x},oldsymbol{y})=g_J(oldsymbol{y})P_J(oldsymbol{y},oldsymbol{x})$  for all  $oldsymbol{x},\,oldsymbol{y}\in\mathbb{Z}^k$ 

2.  $g_J$  is invariant for  $\mathscr{X}$ .

3.  $\mathscr{X}_J$  is reversal of  $\mathscr{X}$  with respect to  $g_J$ .

Proof

Part (a) follows from simple substitution. Parts (b) and (c) follow from (a) and the general theory.

Note that when  $J = \emptyset$ ,  $g_J = \mathbf{1}$  and when  $J = \{1, 2, ..., k\}$ ,  $g_J = g$ , the invariant function introduced above. So in the completely non-symmetric case where  $p_i \neq q_i$  for every  $i \in \{1, 2, ..., k\}$ , the random walk  $\mathscr{X}$  has  $2^k$  positive invariant functions that are linearly independent, and  $\mathscr{X}$  is reversible with respect to one of them.

## 16.15: Introduction to Continuous-Time Markov Chains

This section begins our study of Markov processes in continuous time and with discrete state spaces. Recall that a Markov process with a discrete state space is called a *Markov chain*, so we are studying *continuous-time Markov chains*. It will be helpful if you review the section on general Markov processes, at least briefly, to become familiar with the basic notation and concepts. Also, discrete-time chains plays a fundamental role, so you will need review this topic also.

We will study continuous-time Markov chains from different points of view. Our point of view in this section, involving holding times and the embedded discrete-time chain, is the most intuitive from a probabilistic point of view, and so is the best place to start. In the next section, we study the transition probability matrices in continuous time. This point of view is somewhat less intuitive, but is closest to how other types of Markov processes are treated. Finally, in the third introductory section we study the Markov chain from the view point of potential matrices. This is the least intuitive approach, but analytically one of the best. Naturally, the interconnections between the various approaches are particularly important.

#### **Preliminaries**

As usual, we start with a probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ , so that  $\Omega$  is the set of outcomes,  $\mathscr{F}$  the  $\sigma$ -algebra of events, and  $\mathbb{P}$  the probability measure on the sample space  $(\Omega, \mathscr{F})$ . The time space is  $([0, \infty), \mathscr{F})$  where as usual,  $\mathscr{F}$  is the Borel  $\sigma$ -algebra on  $[0, \infty)$  corresponding to the standard Euclidean topology. The state space is  $(S, \mathscr{F})$  where S is countable and  $\mathscr{F}$  is the power set of S. So every subset of S is measurable, as is every function from S to another measurable space. Recall that  $\mathscr{F}$  is also the Borel  $\sigma$  algebra corresponding to the discrete topology on S. With this topology, every function from S to another topological space is continuous. Counting measure # is the natural measure on  $(S, \mathscr{F})$ , so in the context of the general introduction, integrals over S are simply sums. Also, kernels on S can be thought of as matrices, with rows and sums indexed by S. The left and right kernel operations are generalizations of matrix multiplication.

Suppose now that  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  is stochastic process with state space  $(S, \mathscr{S})$ . For  $t \in [0, \infty)$ , let  $\mathscr{F}_t^0 = \sigma\{X_s : s \in [0, t]\}$ , so that  $\mathscr{F}_t^0$  is the  $\sigma$ -algebra of events defined by the process up to time t. The collection of  $\sigma$ -algebra  $\mathfrak{F}_t^0 : t \in [0, \infty)\}$  is the natural filtration associated with  $\mathbf{X}$ . For technical reasons, it's often necessary to have a filtration  $\mathfrak{F} = \{\mathscr{F}_t : t \in [0, \infty)\}$  that is slightly finer than the natural one, so that  $\mathscr{F}_t^0 \subseteq \mathscr{F}_t$  for  $t \in [0, \infty)$  (or in equivlaent jargon,  $\mathbf{X}$  is adapted to  $\mathfrak{F}$ ). See the general introduction for more details on the common ways that the natural filtration is refined. We will also let  $\mathscr{G}_t = \sigma\{X_s : s \in [t, \infty)\}$ , the  $\sigma$ -algebra of events defined by the process from time t onward. If t is thought of as the present time, then  $\mathscr{F}_t$  is the collection of events in the past and  $\mathscr{G}_t$  is the collection of events in the future.

It's often necessary to impose assumptions on the continuity of the process X in time. Recall that X is *right continuous* if  $t \mapsto X_t(\omega)$  is right continuous on  $[0, \infty)$  for every  $\omega \in \Omega$ , and similarly X has left limits if  $t \mapsto X_t(\omega)$  has left limits on  $(0, \infty)$  for every  $\omega \in \Omega$ . Since S has the discrete topology, note that if X is right continuous, then for every  $t \in [0, \infty)$  and  $\omega \in \Omega$ , there exists  $\epsilon$  (depending on t and  $\omega$ ) such that  $X_{t+s}(\omega) = X_t(\omega)$  for  $s \in [0, \epsilon)$ . Similarly, if X has left limits, then for every  $t \in (0, \infty)$  and  $\omega \in \Omega$  there exists  $\delta$  (depending on t and  $\omega$ ) such that  $X_{t-s}(\omega)$  is constant for  $s \in (0, \delta)$ .

#### The Markov Property

There are a number of equivalent ways to state the Markov property. At the most basic level, the property states that the *past and future are conditionally independent, given the present.* 

The process 
$$\mathbf{X} = \{X_t : t \in [0, \infty)\}$$
 is a *Markov chain* on *S* if for every  $t \in [0, \infty)$ ,  $A \in \mathscr{F}_t$ , and  $B \in \mathscr{G}_t$ ,  
 $\mathbb{P}(A \cap B \mid X_t) = \mathbb{P}(A \mid X_t)\mathbb{P}(B \mid X_t)$ 
(16.15.1)

Another version is that the conditional distribution of a state in the future, given the past, is the same as the conditional distribution just given the present state.

The process 
$$X = \{X_t : t \in [0, \infty)\}$$
 is a Markov chain on  $S$  if for every  $s, t \in [0, \infty)$ , and  $x \in S$ ,  

$$\mathbb{P}(X_{s+t} = x \mid \mathscr{F}_s) = \mathbb{P}(X_{s+t} = x \mid X_s)$$
(16.15.2)

Technically, in the last two definitions, we should say that X is a Markov process *relative to* the filtration  $\mathfrak{F}$ . But recall that if X satisfies the Markov property relative to a filtration, then it satisfies the Markov property relative to any coarser filtration, and in particular, relative to the natural filtration. For the natural filtration, the Markov property can also be stated without explicit reference to  $\sigma$ -algebras, although at the cost of additional clutter:

The process  $X = \{X_t : t \in [0, \infty)\}$  is a Markov chain on S if and only if for every  $n \in \mathbb{N}_+$ , time sequence  $(t_1, t_2, \dots, t_n) \in [0, \infty)^n$  with  $t_1 < t_2 < \dots < t_n$ , and state sequence  $(x_1, x_2, \dots, x_n) \in S^n$ ,

$$\mathbb{P}(X_{t_n} = x_n \mid X_{t_1} = x_1, X_{t_2} = x_2, \dots X_{t_{n-1}} = x_{n-1}) = \mathbb{P}(X_{t_n} = x_n \mid X_{t_{n-1}} = x_{n-1})$$
(16.15.3)

As usual, we also assume that our Markov chain X is *time homogeneous*, so that  $\mathbb{P}(X_{s+t} = y \mid X_s = x) = \mathbb{P}(X_t = y \mid X_0 = x)$  for  $s, t \in [0, \infty)$  and  $x, y \in S$ . So, for a homogeneous Markov chain on S, the process  $\{X_{s+t} : t \in [0, \infty)\}$  given  $X_s = x$ , is independent of  $\mathscr{F}_s$  and equivalent to the process  $\{X_t : t \in [0, \infty)\}$  given  $X_0 = x$ , for every  $s \in [0, \infty)$  and  $x \in S$ . That is, if the chain is in state  $x \in S$  at a particular time  $s \in [0, \infty)$ , it does not matter how the chain *got to x*; the chain essentially starts over in state x.

## The Strong Markov Property

Random times play an important role in the study of continuous-time Markov chains. It's often necessary to allow random times to take the value  $\infty$ , so formally, a random time  $\tau$  is a random variable on the underlying sample space  $(\Omega, \mathscr{F})$  taking values in  $[0, \infty]$ . Recall also that a random time  $\tau$  is a stopping time (also called a *Markov time* or an *optional time*) if  $\{\tau \leq t\} \in \mathscr{F}_t$  for every  $t \in [0, \infty)$ . If  $\tau$  is a stopping time, the  $\sigma$ -algebra associated with  $\tau$  is

$$\mathscr{F}_{\tau} = \{A \in \mathscr{F} : A \cap \{\tau \le t\} \in \mathscr{F}_t \text{ for all } t \in [0, \infty)\}$$

$$(16.15.4)$$

So  $\mathscr{F}_{\tau}$  is the collection of events up to the random time  $\tau$  in the same way that  $\mathscr{F}_t$  is the collection of events up to the deterministic time  $t \in [0, \infty)$ . We usually want the Markov property to extend from deterministic times to stopping times.

The process 
$$m{X}=\{X_t:t\in[0,\infty)\}$$
 is a *strong Markov chain* on  $S$  if for every stopping time  $au,t\in[0,\infty)$ , and  $x\in S$ ,

$$\mathbb{P}(X_{\tau+t} = x \mid \mathscr{F}_{\tau}) = \mathbb{P}(X_{\tau+t} = x \mid X_{\tau})$$
(16.15.5)

So, for a homogeneous strong Markov chain on S, the process  $\{X_{\tau+t} : t \in [0,\infty)\}$  given  $X_{\tau} = x$ , is independent of  $\mathscr{P}_{\tau}$  and equivalent to the process  $\{X_t : t \in [0,\infty)\}$  given  $X_0 = x$ , for every stopping time  $\tau$  and  $x \in S$ . That is, if the chain is in state  $x \in S$  at a stopping time  $\tau$ , then the chain essentially starts over at x, independently of the past.

## Holding Times and the Jump Chain

For our first point of view, we sill study *when* and *how* our Markov chain X changes state. The discussion depends heavily on properties of the exponential distribution, so we need a quick review.

## The Exponential Distribution

A random variable  $\tau$  has the *exponential distribution* with rate parameter  $r \in (0, \infty)$  if  $\tau$  has a continuous distribution on  $[0, \infty)$  with probability density function f given by  $f(t) = re^{-rt}$  for  $t \in [0, \infty)$ . Equivalently, the right distribution function  $F^c$  is given by

$$F^{c}(t) = \mathbb{P}(\tau > t) = e^{-rt}, \quad t \in [0, \infty)$$
 (16.15.6)

The mean of the distribution is 1/r and the variance is  $1/r^2$ . The exponential distribution has an amazing number of characterizations. One of the most important is the *memoryless property* which states that a random variable  $\tau$  with values in  $[0, \infty)$  has an exponential distribution if and only if the conditional distribution of  $\tau - s$  given  $\tau > s$  is the same as the distribution of  $\tau$  itself, for every  $s \in [0, \infty)$ . It's easy to see that the memoryless property is equivalent to the *law of exponents* for right distribution function  $F^c$ , namely  $F^c(s+t) = F^c(s)F^c(t)$  for  $s, t \in [0, \infty)$ . Since  $F^c$  is right continuous, the only solutions are exponential functions.

For our study of continuous-time Markov chains, it's helpful to extend the exponential distribution to two degenerate cases,  $\tau = 0$  with probability 1, and  $\tau = \infty$  with probability 1. In terms of the parameter, the first case corresponds to  $r = \infty$  so that  $F(t) = \mathbb{P}(\tau > t) = 0$  for every  $t \in [0, \infty)$ , and the second case corresponds to r = 0 so that  $F(t) = \mathbb{P}(\tau > t) = 1$  for every  $t \in [0, \infty)$ . Note that in both cases, the function F satisfies the law of exponents, and so corresponds to a memoryless distribution in a general sense. In all cases, the mean of the exponential distribution with parameter  $r \in [0, \infty)$  is 1/r, where we interpret  $1/0 = \infty$  and  $1/\infty = 0$ .

## Holding Times

The Markov property implies the memoryless property for the random time when a Markov process first leaves its initial state. It follows that this random time must have an exponential distribution.

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  is a Markov chain on S, and let  $\tau = \inf\{t \in [0, \infty) : X_t \neq X_0\}$ . For  $x \in S$ , the conditional distribution of  $\tau$  given  $X_0 = x$  is exponential with parameter  $\lambda(x) \in [0, \infty]$ .

Proof

Let  $x \in S$  and  $s \in [0, \infty)$ . The events  $X_0 = x$  and  $\tau > s$  imply  $X_s = x$ . By the Markov property, given  $X_s = x$ , the chain starts over at time s in state x, independent of  $\{X_0 = x\}$  and  $\{\tau > s\}$ , since both events are in  $\mathscr{F}_s$ . Hence for  $t \in [0, \infty)$ ,

$$\mathbb{P}(\tau > t + s \mid X_0 = x, \tau > s) = \mathbb{P}(\tau > t + s \mid X_0 = x, X_s = x, \tau > s) = \mathbb{P}(\tau > t \mid X_0 = x)$$
(16.15.7)

It follows that  $\tau$  has the memoryless property, and hence has an exponential distribution with parameter  $\lambda(x) \in [0, \infty]$ .

So, associated with the Markov chain X on S is a function  $\lambda : S \to [0, \infty]$  that gives the exponential parameters for the holding times in the states. Considering the ordinary exponential distribution, and the two degenerate versions, we are led to the following classification of states:

Suppose again that  $X = \{X_t : t \in [0, \infty)\}$  is a Markov chain on S with exponential parameter function  $\lambda$ . Let  $x \in S$ .

1. If  $\lambda(x) = 0$  then  $\mathbb{P}(\tau = \infty \mid X_0 = x) = 1$ , and x is said to be an *absorbing state*. 2. If  $\lambda(x) \in (0, \infty)$  then  $\mathbb{P}(0 < \tau < \infty \mid X_0 = x) = 1$  and x is said to be an *stable state*. 3. If  $\lambda(x) = \infty$  then  $\mathbb{P}(\tau = 0 \mid X_0 = x) = 1$ , and x is said to be an *instantaneous state*.

As you can imagine, an instantaneous state corresponds to weird behavior, since the chain starting in the state leaves the state at times arbitrarily close to 0. While mathematically possible, instantaneous states make no sense in most applications, and so are to be avoided. Also, the proof of the last result has some technical holes. We did not really show that  $\tau$  is a valid random time, let alone a stopping time. Fortunately, one of our standard assumptions resolves these problems.

Suppose again that  $X = \{X_t : t \in [0, \infty)\}$  is a Markov chain on *S*. If the process *X* and the filtration  $\mathfrak{F}$  are right continuous, then

1.  $\tau$  is a stopping time.

2.  $\boldsymbol{X}$  has no instantaneous states.

3.  $\mathbb{P}(X_{ au} 
eq x \mid X_0 = x) = 1$  if  $x \in S$  is stable.

4. *X* is a strong Markov process.

Proof

1. Let  $t \in [0,\infty)$ . By right continuity,

$$\{\tau < t\} = \{X_s \neq X_0 \text{ for some } s \in (0, t)\} = \{X_s \neq X_0 \text{ for some rational } s \in (0, t)\}$$
(16.15.8)

But for  $s \in (0, t)$ ,  $\{X_s \neq X_0\} \in \mathscr{F}_s \subseteq \mathscr{F}_t$ . The last event in the displayed equation is a countable union, so  $\{\tau < t\} \in \mathscr{F}_t$ . Since  $\mathfrak{F}$  is right continuous,  $\tau$  is a stopping time.

- 2. Suppose that  $\omega \in \Omega$  and  $X_0(\omega) = x$ . Since  $\boldsymbol{X}$  is right continuous, there exists  $\epsilon > 0$  such that  $X_t(\omega) = x$  for  $0 \le t < \epsilon$  and hence  $\tau(\omega) \ge \epsilon > 0$ . So  $\mathbb{P}(\tau > 0 \mid X_0 = x) = 1$ .
- 3. Similarly, suppose that  $\omega \in \Omega$  and that  $X_0(\omega) = x$  and  $X_{\tau(\omega)}(\omega) = y$ . Since  $\mathbf{X}$  is right continuous, there exists  $\epsilon > 0$  such that  $X_t(\omega) = y$  for  $\tau(\omega) \le t < \tau(\omega) + \epsilon$ . But by definition of  $\tau(\omega)$ , there exists  $t \in (\tau(\omega), \tau(\omega) + \epsilon)$  with  $X_t(\omega) \ne x$ . Hence  $\mathbb{P}(X_\tau \ne x \mid X_0 = x) = 1$ .

There is actually a converse to part (b) that states that if X has no instantaneous states, then there is a version of X that is right continuous. From now on, we will assume that our Markov chains are right continuous with probability 1, and hence have no instantaneous states. On the other hand, absorbing states are perfectly reasonable and often do occur in applications. Finally, if the chain enters a stable state, it will stay there for a (proper) exponentially distributed time, and then leave.

#### The Jump Chain

Without instantaneous states, we can now construct a sequence of stopping times. Basically, we let  $\tau_n$  denote the *n*th time that the chain changes state for  $n \in \mathbb{N}_+$ , unless the chain has previously been caught in an absorbing state. Here is the formal construction:

Suppose again that  $X = \{X_t : t \in [0, \infty)\}$  is a Markov chain on S. Let  $\tau_0 = 0$  and  $\tau_1 = \inf\{t \in [0, \infty) : X_t \neq X_0\}$ . Recursively, suppose that  $\tau_n$  is defined for  $n \in \mathbb{N}_+$ . If  $\tau_n = \infty$  let  $\tau_{n+1} = \infty$ . Otherwise, let

$$\tau_{n+1} = \inf\{t \in [\tau_n, \infty) : X_t \neq X_{\tau_n}\}$$
(16.15.9)

Let  $M = \sup\{n \in \mathbb{N} : \tau_n < \infty\}$  .

In the definition of M, of course,  $\sup(\mathbb{N}) = \infty$ , so M is the number of changes of state. If  $M < \infty$ , the chain was sucked into an absorbing state at time  $\tau_M$ . Since we have ruled out instantaneous states, the sequence of random times in strictly increasing up until the (random) term M. That is, with probability 1, if  $n \in \mathbb{N}$  and  $\tau_n < \infty$  then  $\tau_n < \tau_{n+1}$ . Of course by construction, if  $\tau_n = \infty$  then  $\tau_{n+1} = \infty$ . The increments  $\tau_{n+1} - \tau_n$  for  $n \in \mathbb{N}$  with n < M are the times spent in the states visited by X. The process at the random times when the state changes forms an embedded discrete-time Markov chain.

Suppose again that  $X = \{X_t : t \in [0, \infty)\}$  is a Markov chain on S. Let  $\{\tau_n : n \in \mathbb{N}\}$  denote the stopping times and M the random index, as defined above. For  $n \in \mathbb{N}$ , let  $Y_n = X_{\tau_n}$  if  $n \leq M$  and  $Y_n = X_{\tau_M}$  if n > M. Then  $Y = \{Y_n : n \in \mathbb{N}\}$  is a (homogenous) discrete-time Markov chain on S, known as the *jump chain* of X.

Proof

For  $n \in \mathbb{N}$  let  $\mathscr{G}_n = \sigma\{Y_0, Y_1, \ldots, Y_n\}$ , the  $\sigma$ -algebra of events for the process Y, up to the discrete time n. Let  $x \in S$ . If x is stable, then given  $Y_n = x$ , the random times  $\tau_n$  and  $\tau_{n+1}$  are finite with probability 1. (Note that we cannot get to x from an absorbing state.) So

$$\mathbb{P}(Y_{n+1} = y \mid Y_n = x, \mathscr{G}_n) = \mathbb{P}\left(X_{\tau_{n+1}} = y \mid X_{\tau_n} = x, \mathscr{G}_n\right), \quad y \in S$$

$$(16.15.10)$$

But by the strong Markov property, given  $X_{\tau_n} = x$ , the chain starts over at time  $\tau_n$  in state x, independent of  $\mathscr{G}_n \subseteq \mathscr{F}_{\tau_n}$ . Hence

$$\mathbb{P}(Y_{n+1} = y \mid Y_n = x, \mathscr{G}_n) = \mathbb{P}(X_{\tau} = y \mid X_0 = x), \quad y \in S$$
  
(16.15.11)

On the other hand, if x is an absorbing state, then by construction,

$$\mathbb{P}(Y_{n+1} = y \mid Y_n = x, \mathscr{G}_n) = I(x, y), \quad y \in S \tag{16.15.12}$$

where I is the identity matrix on S.

As noted in the proof, the one-step transition probability matrix Q for the jump chain  $m{Y}$  is given for  $(x,y)\in S^2$  by

$$Q(x,y) = \begin{cases} \mathbb{P}(X_{\tau} = y \mid X_0 = x), & x \text{ stable} \\ I(x,y), & x \text{ absorbing} \end{cases}$$
(16.15.13)

where I is the identity matrix on S. Of course Q satisfies the usual properties of a probability matrix on S, namely  $Q(x, y) \ge 0$  for  $(x, y) \in S^2$ and  $\sum_{y \in S} Q(x, y) = 1$  for  $x \in S$ . But Q satisfies another interesting property as well. Since the state actually *changes* at time  $\tau$  starting in a stable state, we must have Q(x, x) = 0 if x is stable and Q(x, x) = 1 if x is absorbing.

Given the initial state, the holding time and the next state are independent.

If 
$$x, y \in S$$
 and  $t \in [0,\infty)$  then  $\mathbb{P}(Y_1 = y, au_1 > t \mid Y_0 = x) = Q(x,y)e^{-\lambda(x)t}$   
Proof

Suppose that x is a stable state, so that given  $Y_0 = X_0 = x$ , the stopping time  $\tau_1 = \tau$  has a proper exponential distribution with parameter  $\lambda(x) \in (0, \infty)$ . Note that

$$\mathbb{P}(Y_1 = y, \tau_1 > t \mid Y_0 = x) = \mathbb{P}(X_\tau = y, \tau > t \mid X_0 = x) = \mathbb{P}(X_\tau = y \mid \tau > t, X_0 = x)\mathbb{P}(\tau > t \mid X_0 = x)$$
(16.15.14)

Note that if  $X_0 = x$  and  $\tau > t$  then  $X_t = x$  also. By the Markov property, given  $X_t = x$ , the chain starts over at time t in state x, independent of  $\{X_0 = x\}$  and  $\{\tau > t\}$ , both events in  $\mathscr{F}_t$ . Hence

$$\mathbb{P}(X_{\tau} = y \mid \tau > t, X_0 = x) = \mathbb{P}(X_{\tau} = y \mid X_t = x, \tau > t, X_0 = x) = \mathbb{P}(X_{\tau} = y \mid X_0 = x) = Q(x, y)$$
(16.15.15)

Of course  $\mathbb{P}( au > t \mid X_0 = x) = e^{-\lambda(x)t}$  .

If x is an absorbing state then  $\mathbb{P}( au=\infty\mid X_0=x)=1$  ,  $\mathbb{P}(Y_1=x\mid Y_0=x)=1$  , and  $\lambda(x)=0$  . Hence

$$\mathbb{P}(Y_1 = y, \tau_1 > t \mid Y_0 = x) = I(x, y) = Q(x, y)e^{-\lambda(x)t}$$
(16.15.16)

The following theorem is a generalization. The changes in state and the holding times are independent, given the initial state.

Suppose that  $n \in \mathbb{N}_+$  and that  $(x_0, x_1, \dots, x_n)$  is a sequence of stable states and  $(t_1, t_2, \dots, t_n)$  is a sequence in  $[0, \infty)$ . Then

$$\mathbb{P}(Y_1=x_1, au_1>t_1,Y_2=x_2, au_2- au_1>t_2,\dots,Y_n=x_n, au_n- au_{n-1}>t_n\mid Y_0=x_0)=Q(x_0,x_1)e^{-\lambda(x_0)t_1}Q(x_1,x_2)e^{-\lambda(x_1)t_2}\cdots Q(x_{n-1},x_n)e^{-\lambda(x_{n-1})t_n}$$

Proof

The proof is by induction, and the essence is captured in the case n = 2. So suppose that  $x_0$ ,  $x_1$ ,  $x_2$  are stable states and  $t_1$ ,  $t_2 \in [0, \infty)$ . Then

$$egin{aligned} \mathbb{P}(Y_1 = x_1, au_1 > t_1, Y_2 = x_2, au_2 - au_1 > t_2 \mid Y_0 = x_0) \ = \mathbb{P}(Y_2 = x_2, au_2 - au_1 > t_2 \mid X_0 = x, Y_1 = x_1, au_1 > t_1) \mathbb{P}(Y_1 = x_1, au_1 > t_1 \mid Y_0 = x_0) \end{aligned}$$

But  $\mathbb{P}(Y_1 = x_1, \tau_1 > t_1 \mid Y_0 = x_0) = Q(x_0, x_1)e^{-\lambda(x_0)t_1}$  by the previous theorem. Next, by definition,

$$\mathbb{P}(Y_2 = x_2, \tau_2 - \tau_1 > t_2 \mid X_0 = x, Y_1 = x_1, \tau_1 > t_1) = \mathbb{P}(X_{\tau_2} = x_2, \tau_2 - \tau_1 > t_2 \mid X_0 = x_0, X_{\tau_1} = x_1, \tau_1 > t_1) \quad (16.15.17)$$

But by the strong Markov property, given  $X_{\tau_1} = x_1$ , the chain starts over at time  $\tau_1$  in state x, independent of the events  $\{X_0 = x_0\}$  and  $\{\tau_1 > t_1\}$  (both events in  $\mathscr{F}_{\tau_1}$ ). Hence using the previous theorem again,

$$\mathbb{P}(Y_2 = x_2, \tau_2 - \tau_1 > t_2 \mid X_0 = x, Y_1 = x_1, \tau_1 > t_1) = \mathbb{P}(X_\tau = x_2, \tau > t_2 \mid X_0 = x_1) = Q(x_1, x_2)e^{-\lambda(x_1)t_2}$$
(16.15.18)

#### Regularity

We now know quite a bit about the structure of a continuous-time Markov chain  $X = \{X_t : t \in [0, \infty)\}$  (without instantaneous states). Once the chain enters a given state  $x \in S$ , the holding time in state x has an exponential distribution with parameter  $\lambda(x) \in [0, \infty)$ , after which the next state  $y \in S$  is chosen, independently of the holding time, with probability Q(x, y) However, we don't know everything about the chain. For the sequence  $\{\tau_n : n \in \mathbb{N}\}$  defined above, let  $\tau_{\infty} = \lim_{n \to \infty} \tau_n$ , which exists in  $(0, \infty]$  of course, since the sequence is increasing. Even though the holding time in a state is positive with probability 1, it's possible that  $\tau_{\infty} < \infty$  with positive probability, in which case we know nothing about  $X_t$ 

for  $t \ge \tau_{\infty}$ . The event { $\tau_{\infty} < \infty$ } is known as *explosion*, since it means that the **X** makes infinitely many transitions before the finite time  $\tau_{\infty}$ . While not as pathological as the existence of instantaneous states, explosion is still to be avoided in most applications.

A Markov chain  $X = \{X_t : t \in [0, \infty)\}$  on *S* is *regular* if each of the following events has probability 1:

1.  $\boldsymbol{X}$  is right continuous. 2.  $\tau_n \to \infty$  as  $n \to \infty$ .

There is a simple condition on the exponential parameters and the embedded chain that is equivalent to condition (b).

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  is a right-continuous Markov chain on S with exponential parameter function  $\lambda$  and embedded chain  $Y = (Y_0, Y_1, \ldots)$ . Then  $\tau_n \to \infty$  as  $n \to \infty$  with probability 1 if and only if  $\sum_{n=0}^{\infty} 1/\lambda(Y_n) = \infty$  with probability 1. Proof

Given  $\mathbf{Y} = (y_0, y_1, \ldots)$ , the distribution of  $\tau_{\infty} = \lim_{n \to \infty} \tau_n$  is the distribution of  $T_{\infty} = \sum_{n=0}^{\infty} T_n$  where  $(T_0, T_1, \ldots)$  are independent, and  $T_n$  has the exponential distribution with parameter  $\lambda(y_n)$ . Note that  $\mathbb{E}(T_{\infty}) = \sum_{n=0}^{\infty} 1/\lambda(y_n)$ . In the section on the exponential distribution, it's shown that  $\mathbb{P}(T_{\infty} = \infty) = 1$  if and only if  $\mathbb{E}(T_{\infty}) = \infty$ .

If  $\lambda$  is bounded, then  $\boldsymbol{X}$  is regular.

Suppose that  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  is a Markov chain on S with exponential parameter function  $\lambda$ . If  $\lambda$  is bounded, then  $\mathbf{X}$  is regular. Proof

Suppose that  $\lambda(x) \leq r$  for  $x \in S$ , where  $r \in (0, \infty)$ . Then in particular, X has no instantaneous states and so is right continuous. Moreover,  $1/\lambda(x) \geq 1/r$  for  $x \in S$  so  $\sum_{n=0}^{\infty} 1/\lambda(Y_n) = \infty$  with probability 1, where as usual,  $Y = (Y_0, Y_1, \ldots)$  is the jump chain of X.

Here is another sufficient condition that is useful when the state space is infinite.

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  is a Markov chain on S with exponential parameter function  $\lambda : S \to [0, \infty)$ . Let  $S_+ = \{x \in S : \lambda(x) > 0\}$ . Then X is regular if

$$\sum_{x \in S_+} \frac{1}{\lambda(x)} = \infty \tag{16.15.19}$$

Proof

By assumption,  $\lambda(x) < \infty$  for  $x \in S$ , so there are no instantaneous states and so we can take **X** to be right continuous. Next,

$$\sum_{n=0}^{\infty} \frac{1}{\lambda(Y_n)} = \sum_{n=0}^{\infty} \sum_{x \in S} \frac{1}{\lambda(x)} \mathbf{1}(Y_n = x) = \sum_{x \in S} \frac{1}{\lambda(x)} \sum_{n=0}^{\infty} \mathbf{1}(Y_n = x) = \sum_{x \in S} \frac{N_x}{\lambda(x)}$$
(16.15.20)

where  $N_x = \sum_{n=0}^{\infty} \mathbf{1}(Y_n = x)$  is the number of times that the jump chain  $\mathbf{Y}$  is in state x. Suppose that  $\sum_{x \in S_+} 1/\lambda(x) = \infty$ . Note that it must be the case that  $S_+$ , and hence S, is infinite. With probability 1, either  $\mathbf{Y}$  enters an absorbing state (a state  $x \in S$  with  $\lambda(x) = 0$ ), or  $N_x = \infty$  for some  $x \in S_+$ , or  $N_x \ge 1$  for infinitely many  $x \in S_+$ . In any case,

$$\sum_{n=0}^{\infty} \frac{1}{\lambda(Y_n)} = \sum_{x \in S} \frac{N_x}{\lambda(x)} = \infty$$
(16.15.21)

As a corollary, note that if *S* is finite then  $\lambda$  is bounded, so a continuous-time Markov chain on a finite state space is regular. So to review, if the exponential parameter function  $\lambda$  is finite, the chain **X** has no instantaneous states. Even better, if  $\lambda$  is bounded or if the conditions in the last theorem are satisfied, then **X** is regular. A continuous-time Markov chain with bounded exponential parameter function  $\lambda$  is called *uniform*, for reasons that will become clear in the next section on transition matrices. As we will see in later section, a uniform continuous-time Markov chain can be constructed from a discrete-time chain and an independent Poisson process. For the next result, recall that to say that **X** has *left limits* with probability 1 means that the random function  $t \mapsto X_t$  has limits from the left on  $(0, \infty)$  with probability 1.

If  $X = \{X_t : t \in [0, \infty)\}$  is regular then X has left limits with probability 1.

Proof

Suppose first that there are no absorbing states. Under the assumptions, with probability 1,  $0 < \tau_n < \infty$  for each  $n \in \mathbb{N}$  and  $\tau_n \to \infty$  as  $n \to \infty$ . Moreover,  $X_t = Y_n$  for  $t \in [\tau_n, \tau_{n+1})$  and  $n \in \mathbb{N}$ . So  $t \mapsto X_t$  has left limits on  $(0, \infty)$  with probability 1. The same basic argument works with absorbing states, except that possibly  $\tau_{n+1} = \infty$ .

Thus, our standard assumption will be that  $X = \{X_t : t \in [0, \infty)\}$  is a regular Markov chain on S. For such a chain, the behavior of X is completely determined by the exponential parameter function  $\lambda$  that governs the holding times, and the transition probability matrix Q of the

jump chain Y. Conversely, when modeling real stochastic systems, we often start with  $\lambda$  and Q. It's then relatively straightforward to construct the continuous-time Markov chain that has these parameters. For simplicity, we will assume that there are no absorbing states. The inclusion of absorbing states is not difficult, but mucks up the otherwise elegant exposition.

Suppose that  $\lambda : S \to (0, \infty)$  is bounded and that Q is a probability matrix on S with the property that Q(x, x) = 0 for every  $x \in S$ . The regular, continuous-time Markov chain  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  with exponential parameter function  $\lambda$  and jump transition matrix Q can be constructed as follows:

- 1. First construct the jump chain  $\mathbf{Y} = (Y_0, Y_1, ...)$  having transition matrix Q.
- 2. Next, given  $\mathbf{Y} = (x_0, x_1, ...)$ , the transition times  $(\tau_1, \tau_2, ...)$  are constructed so that the holding times  $(\tau_1, \tau_2 \tau_1, ...)$  are independent and exponentially distributed with parameters  $(\lambda(x_0), \lambda(x_1), ...)$

3. Again given  $Y = (x_0, x_1, \ldots)$ , define  $X_t = x_0$  for  $0 \le t < \tau_1$  and for  $n \in \mathbb{N}_+$ , define  $X_t = x_n$  for  $\tau_n \le t < \tau_{n+1}$ ).

#### Additional details

Using product sets and product measures, it's straightforward to construct a probability space  $(\Omega, \mathscr{F}, \mathbb{P})$  with the following objects and properties:

- 1.  $\mathbf{Y} = (Y_0, Y_1, \ldots)$  is a Markov chain on *S* with transition matrix *Q*.
- 2.  $T = \{T_x : x \in S\}$  is a collection of independent random variables with values in  $[0, \infty)$  such that  $T_x$  has the exponential distribution with parameter  $\lambda(x)$  for each  $x \in S$ .
- 3. *Y* and *T* are independent.

Define  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  as follows: First,  $\tau_1 = T_{Y_0}$  and  $X_t = Y_0$  for  $0 \le t < \tau_1$ . Recursively, if  $X_t$  is defined on  $[0, \tau_n)$ , let  $\tau_{n+1} = \tau_n + T_{Y_n}$  and then let  $X_t = Y_n$  for for  $\tau_n \le t < \tau_{n+1}$ . Since  $\lambda$  is bounded,  $\tau_n \to \infty$  as  $n \to \infty$ , so  $X_t$  is well defined for  $t \in [0, \infty)$ . By construction,  $t \mapsto X_t$  is right continuous and has left limits. The Markov property holds by the memoryless property of the exponential distribution and the fact that  $\mathbf{Y}$  is a Markov chain. Finally, by construction,  $\mathbf{X}$  has exponential parameter function  $\lambda$  and jump chain  $\mathbf{Y}$ .

Often, particularly when S is finite, the essential structure of a standard, continuous-time Markov chain can be succinctly summarized with a graph.

Suppose again that  $X = \{X_t : t \in [0, \infty)\}$  is a regular Markov chain on S, with exponential parameter function  $\lambda$  and embedded transition matrix Q. The *state graph* of X is the graph with vertex set S and directed edge set  $E = \{(x, y) \in S^2 : Q(x, y) > 0\}$ . The graph is *labeled* as follows:

1. Each vertex  $x \in S$  is labeled with the exponential parameter  $\lambda(x)$ .

2. Each edge  $(x, y) \in E$  is labeled with the transition probability Q(x, y)

So except for the labels on the vertices, the state graph of X is the same as the state graph of the discrete-time jump chain Y. That is, there is a directed edge from state x to state y if and only if the chain, when in x, can move to y after the random holding time in x. Note that the only loops in the state graph correspond to absorbing states, and for such a state there are no outward edges.

Let's return again to the construction above of a continuous-time Markov chain from the jump transition matrix Q and the exponential parameter function  $\lambda$ . Again for simplicity, assume there are no absorbing states. We assume that Q(x, x) = 0 for all  $x \in S$ , so that the state really does *change* at the transition times. However, if we drop this assumption, the construction still produces a continuous-time Markov chain, but with an altered jump transition matrix and exponential parameter function.

Suppose that Q is a transition matrix on  $S \times S$  with Q(x, x) < 1 for  $x \in S$ , and that  $\lambda : S \to (0, \infty)$  is bounded. The stochastic process  $X = \{X_t : t \in [0, \infty)\}$  constructed above from Q and  $\lambda$  is a regular, continuous-time Markov chain with exponential parameter function  $\tilde{\lambda}$  and jump transition matrix  $\tilde{Q}$  given by

$$egin{aligned} & ilde{\lambda}(x)=\lambda(x)[1-Q(x,x)], \quad x\in S\ & ilde{Q}(x,y)=rac{Q(x,y)}{1-Q(x,x)}, \quad (x,y)\in S^2, \, x
eq y \end{aligned}$$

Proof 1

As before, the fact that X is a continuous-time Markov chain follows from the memoryless property of the exponential distribution and the Markov property of the jump chain Y. By construction,  $t \mapsto X_t$  is right continuous and has left limits. The main point, however, is that  $(\tau_1, \tau_2, \ldots)$  is not necessarily the sequence of transition times, when the state actually changes. So we just need to determine the parameters. Suppose  $X_0 = x \in S$  and let  $\tau = \tau_1$  have the exponential distribution with parameter  $\lambda(x)$ , as in the construction. Let T denote the time when the state actually does change. For  $t \in [0, \infty)$ , the event T > t can happen in two ways: either  $\tau > t$  or  $\tau = s$  for some  $s \in [0, t]$ , the chain jumps back into state x at time s, and the process then stays in x for a period of at least t - s. Thus let  $F_x(t) = \mathbb{P}(T > t \mid X_0 = x)$ . Taking the two cases, conditioning on  $\tau$ , and using the Markov property gives

$$F_x(t) = e^{-\lambda(x)t} + \int_0^t \lambda(x)e^{-\lambda(x)s}Q(x,x)F_x(t-s)ds$$
(16.15.22)

Using the change of variables u = t - s and simplifying gives

$$F_{x}(t) = e^{-\lambda(x)t} \left[ 1 + \lambda(x)Q(x,x) \int_{0}^{t} e^{\lambda(x)u} F_{x}(u) du \right]$$
(16.15.23)

Differentiating with respect to t then gives

$$F'_x(t) = -\lambda(x)[1 - Q(x, x)]F_x(t)$$
(16.15.24)

with the initial condition  $F_x(0) = 1$ . The solution of course is  $F_x(t) = \exp\{-\lambda(x)[1 - Q(x, x)]\}$  for  $t \in [0, \infty)$ . When the state does change, the new state  $y \neq x$  is chosen with probability

$$\mathbb{P}(Y_1 = y \mid Y_0 = x, Y_1 \neq x) = \frac{Q(x, y)}{1 - Q(x, x)} \tag{16.15.25}$$

Proof 2

As in the first proof, we just need to determine the parameters. Given  $X_0 = Y_0 = x$ , the discrete time N when Y first changes state has the geometric distribution on  $\mathbb{N}_+$  with success parameter 1 - Q(x, x). Hence the time until X actually changes state has the distribution of  $T = \sum_{i=1}^{N} U_i$  where  $U = (U_1, U_2, \ldots)$  is a sequence of independent variables, each exponentially distributed with parameter  $\lambda(x)$  and with U independent of N. In the section on the exponential distribution, it is shown that T also has the exponential distribution, but with parameter  $\lambda(x)[1 - Q(x, x)]$ . (The proof is simple using generating functions.) As in the first proof, when the state does change, the new state  $y \neq x$  is chosen with probability

$$\mathbb{P}(Y_1 = y \mid Y_0 = x, Y_1 \neq x) = \frac{Q(x, y)}{1 - Q(x, x)}$$
(16.15.26)

This construction will be important in our study of chains subordinate to the Poisson process.

#### **Transition Times**

The structure of a regular Markov chain on S, as described above, can be explained purely in terms of a family of independent, exponentially distributed random variables. The main tools are some additional special properties of the exponential distribution, that we need to restate in the setting of our Markov chain. Our interest is in how the process evolves among the stable states until it enters an absorbing state (if it does). Once in an absorbing state, the chain stays there forever, so the behavior from that point on is trivial.

Suppose that  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  is a regular Markov chain on S, with exponential parameter function  $\lambda$  and transition probability matrix Q. Define  $\mu(x, y) = \lambda(x)Q(x, y)$  for  $(x, y) \in S^2$ . Then

1. 
$$\lambda(x)=\sum_{y\in S}\mu(x,y)$$
 for  $x\in S.$   
2.  $Q(x,y)=\mu(x,y)/\lambda(x)$ if  $(x,y)\in S^2$  and  $x$  is stable.

The main point is that the new parameters  $\mu(x, y)$  for  $(x, y) \in S^2$  determine the exponential parameters  $\lambda(x)$  for  $x \in S$ , and the transition probabilities Q(x, y) when  $x \in S$  is stable and  $y \in S$ . Of course we know that if  $\lambda(x) = 0$ , so that x is absorbing, then Q(x, x) = 1. So in fact, the new parameters, as specified by the function  $\mu$ , completely determine the old parmeters, as specified by the functions  $\lambda$  and Q. But so what?

Consider the functions  $\mu$ ,  $\lambda$ , and Q as given in the previous result. Suppose that  $T_{x,y}$  has the exponential distribution with parameter  $\mu(x, y)$  for each  $(x, y) \in S^2$  and that  $\{T_{x,y} : (x, y) \in S^2\}$  is a set of independent random variables. Then

1.  $T_x = \inf \{T_{x,y} : y \in S\}$  has the exponential distribution with parameter  $\lambda(x)$  for  $x \in S$ . 2.  $\mathbb{P}(T_x = T_{x,y}) = Q(x,y)$  for  $(x,y) \in S^2$ .

Proof

These are basic results proved in the section on the exponential distribution.

So here's how we can think of a regular, continuous-time Markov chain on S: There is a *timer* associated with each  $(x, y) \in S^2$ , set to the random time  $T_{x,y}$ . All of the timers function independently. When the chain enters state  $x \in S$ , the timers on (x, y) for  $y \in S$  are started simultaneously. As soon as the first alarm goes off for a particular (x, y), the chain immediately moves to state y, and the process repeats. Of course, if  $\mu(x, y) = 0$  then  $T_{x,y} = \infty$  with probability 1, so only the timers with  $\lambda(x) > 0$  and Q(x, y) > 0 matter (these correspond to the non-loop edges in the state graph). In particular, if x is absorbing, then the timers on (x, y) are set to infinity for each y, and no alarm ever sounds.

The new collection of exponential parameters can be used to give an alternate version of the state graph. Again, the vertex set is S and the edge set is  $E = \{(x, y) \in S^2 : Q(x, y) > 0\}$ . But now each edge (x, y) is labeled with the exponential rate parameter  $\mu(x, y)$ . The exponential rate

parameters are closely related to the generator matrix, a matrix of fundamental importance that we will study in the next section.

## Examples and Exercises

#### The Two-State Chain

The two-state chain is the simplest non-trivial, continuous-time Markov chain, but yet this chain illustrates many of the important properties of general continuous-time chains. So consider the Markov chain  $X = \{X_t : t \in [0, \infty)\}$  on the set of states  $S = \{0, 1\}$ , with transition rate  $a \in [0, \infty)$  from 0 to 1 and transition rate  $b \in [0, \infty)$  from 1 to 0.

The transition matrix Q for the embedded chain is given below. Draw the state graph in each case.

1.  $Q = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$  if a > 0 and b > 0, so that both states are stable. 2.  $Q = \begin{bmatrix} 1 & 0 \\ 1 & 0 \end{bmatrix}$  if a = 0 and b > 0, so that a is absorbing and b is stable. 3.  $Q = \begin{bmatrix} 0 & 1 \\ 0 & 1 \end{bmatrix}$  if a > 0 and b = 0, so that a is stable and b is absorbing. 4.  $Q = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$  if a = 0 and b = 0, so that both states are absorbing.

We will return to the two-state chain in subsequent sections.

#### **Computational Exercises**

Consider the Markov chain  $X = \{X_t : t \in [0, \infty)\}$  on  $S = \{0, 1, 2\}$  with exponential parameter function  $\lambda = (4, 1, 3)$  and embedded transition matrix

$$Q = \begin{bmatrix} 0 & \frac{1}{2} & \frac{1}{2} \\ 1 & 0 & 0 \\ \frac{1}{3} & \frac{2}{3} & 0 \end{bmatrix}$$
(16.15.27)

1. Draw the state graph and classify the states.

2. Find the matrix of transition rates.

3. Classify the jump chain in terms of recurrence and period.

4. Find the invariant distribution of the jump chain.

#### Answer

- 1. The edge set is  $E = \{(0, 1), (0, 2), (1, 0), (2, 0), (2, 1)\}$  All states are stable.
- 2. The matrix of transition rates is

0	<b>2</b>	2	
1	0	0	(16.15.28)
1	<b>2</b>	0	

3. The jump chain is irreducible, positive recurrent, and aperiodic.

4. The invariant distribution for the jump chain has PDF

$$f = \begin{bmatrix} \frac{6}{14} & \frac{5}{14} & \frac{3}{14} \end{bmatrix}$$
(16.15.29)

# 16.16: Transition Matrices and Generators of Continuous-Time Chains

## 16. Transition Matrices and Generators of Continuous-Time Chains

#### Preliminaries

This is the second of the three introductory sections on continuous-time Markov chains. Thus, suppose that  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  is a continuous-time Markov chain defined on an underlying probability space  $(\Omega, \mathscr{F}, \mathbb{P})$  and with state space  $(S, \mathscr{S})$ . By the very meaning of *Markov chain*, the set of states S is countable and the  $\sigma$ -algebra  $\mathscr{S}$  is the collection of all subsets of S. So every subset of S is measurable, as is every function from S to another measurable space. Recall that  $\mathscr{S}$  is also the Borel  $\sigma$  algebra corresponding to the discrete topology on S. With this topology, every function from S to another topological space is continuous. Counting measure # is the natural measure on  $(S, \mathscr{S})$ , so in the context of the general introduction, integrals over S are simply sums. Also, kernels on S can be thought of as matrices, with rows and sums indexed by S. The left and right kernel operations are generalizations of matrix multiplication.

A space of functions on *S* plays an important role. Let  $\mathscr{B}$  denote the collection of bounded functions  $f : S \to \mathbb{R}$ . With the usual pointwise definitions of addition and scalar multiplication,  $\mathscr{B}$  is a vector space. The *supremum norm* on  $\mathscr{B}$  is given by

$$||f|| = \sup\{|f(x)| : x \in S\}, \quad f \in \mathscr{B}$$
 (16.16.1)

Of course, if *S* is finite,  $\mathscr{B}$  is the set of all real-valued functions on *S*, and  $\|f\| = \max\{|f(x)| : x \in S\}$  for  $f \in \mathscr{B}$ .

In the last section, we studied X in terms of *when* and *how* the state changes. To review briefly, let  $\tau = \inf\{t \in (0, \infty) : X_t \neq X_0\}$ . Assuming that X is right continuous, the Markov property of X implies the memoryless property of  $\tau$ , and hence the distribution of  $\tau$  given  $X_0 = x$  is exponential with parameter  $\lambda(x) \in [0, \infty)$  for each  $x \in S$ . The assumption of right continuity rules out the pathological possibility that  $\lambda(x) = \infty$ , which would mean that x is an *instantaneous state* so that  $\mathbb{P}(\tau = 0 \mid X_0 = x) = 1$ . On the other hand, if  $\lambda(x) \in (0, \infty)$  then x is a *stable state*, so that  $\tau$  has a proper exponential distribution given  $X_0 = x$  with  $\mathbb{P}(0 < \tau < \infty \mid X_0 = x) = 1$ . Finally, if  $\lambda(x) = 0$  then x is an *absorbing state*, so that  $\mathbb{P}(\tau = \infty \mid X_0 = x) = 1$ . Next we define a sequence of stopping times: First  $\tau_0 = 0$  and  $\tau_1 = \tau$ . Recursively, if  $\tau_n < \infty$  then  $\tau_n = \inf\{t > \tau_n : X_t \neq X_{\tau_n}\}$ , while if  $\tau_n = \infty$  then  $\tau_{n+1} = \infty$ . With  $M = \sup\{n \in \mathbb{N} : \tau_n < \infty\}$  we define  $Y_n = X_{\tau_n}$  if  $n \in \mathbb{N}$  with  $n \leq M$  and  $Y_n = Y_M$  if  $n \in \mathbb{N}$  with n > M. The sequence  $Y = (Y_0, Y_1, \ldots)$  is a discrete-time Markov chain on S with one-step transition matrix Q given by  $Q(x, y) = \mathbb{P}(X_\tau = y \mid X_0 = x)$  if  $x, y \in S$  with x stable, and Q(x, x) = 1 if  $x \in S$  is absorbing. Assuming that X is *regular*, which means that  $\tau_n \to \infty$  as  $n \to \infty$  with probability 1 (ruling out the *explosion* event of infinitely many transitions in finite time), the structure of X is completely determined by the sequence of stopping times  $\tau = (\tau_0, \tau_1, \ldots)$  and the discrete-time jump chain  $Y = (Y_0, Y_1, \ldots)$ . Analytically, the distribution X is determined by the exponential parameter function  $\lambda$  and the one-step transition matrix Q of the jump chain.

In this section, we sill study the Markov chain X in terms of the transition matrices in continuous time and a fundamentally important matrix known as the *generator*. Naturally, the connections between the two points of view are particularly interesting.

#### The Transition Semigroup

#### Definition and basic Properties

The first part of our discussion is very similar to the treatment for a general Markov processes, except for simplifications caused by the discrete state space. We assume that  $X = \{X_t : t \in [0, \infty)\}$  is a Markov chain on *S*.

The *transition probability matrix*  $P_t$  of  $oldsymbol{X}$  corresponding to  $t \in [0,\infty)$  is

$$P_t(x,y) = \mathbb{P}(X_t = y \mid X_0 = x), \quad (x,y) \in S^2$$
(16.16.2)

In particular,  $P_0 = I$  , the identity matrix on S

Proof

The mapping  $y \mapsto P_t(x, y)$  is the PDF of  $X_t$  given  $X_0 = x$ . Hence  $P_t$  is a probability matrix. That is,  $P_t(x, y) \ge 0$  for  $(x, y) \in S^2$  and  $\sum_{y \in S} P_t(x, y) = 1$  for  $x \in S$ . Trivially,  $P_0 = I$  by definition.

Note that since we are assuming that the Markov chain is homogeneous,

$$P_t(x,y) = \mathbb{P}(X_{s+t} = y \mid X_s = x), \quad (x,y) \in S^2$$
 (16.16.3)

for every  $s, t \in [0, \infty)$ . The *Chapman-Kolmogorov equation* given next is essentially yet another restatement of the Markov property. The equation is named for Andrei Kolmogorov and Sydney Chapman,

Suppose that  $P = \{P_t : t \in [0, \infty)\}$  is the collection of transition matrices for the chain X. Then  $P_s P_t = P_{s+t}$  for  $s, t \in [0, \infty)$ . Explicitly,

$$P_{s+t}(x,z) = \sum_{y \in S} P_s(x,y) P_t(y,z), \quad x, \ z \in S$$
 (16.16.4)

Proof

We condition on  $X_s$ .

$$P_{s+t}(x,z) = \mathbb{P}(X_{s+t} = z \mid X_0 = x) = \sum_{y \in S} \mathbb{P}(X_{s+t} = z \mid X_s = y, X_0 = x) \mathbb{P}(X_s = y \mid X_0 = x)$$
(16.16.5)

But by the Markov and time homogeneous properties,

$$\mathbb{P}(X_{s+t} = z \mid X_s = y, X_0 = x) = \mathbb{P}(X_{s+t} = z \mid X_s = y) = P_t(y, z)$$
(16.16.6)

Of course by definition,  $\mathbb{P}(X_s = y \mid X_0 = x) = P_s(x, y)$  . So the first displayed equation above becomes

$$P_{s+t}(x,y) = \sum_{y \in S} P_s(x,y) P_t(y,z) = P_s P_t(x,z)$$
(16.16.7)

Restated in another form of jargon, the collection  $P = \{P_t : t \in [0, \infty)\}$  is a *semigroup* of probability matrices. The semigroup of transition matrices P, along with the initial distribution, determine the finite-dimensional distributions of X.

Suppose that  $X_0$  has probability density function f. If  $(t_1, t_2, ..., t_n) \in [0, \infty)^n$  is a time sequence with  $0 < t_1 < \cdots < t_n$  and  $(x_0, x_1, ..., x_n) \in S^{n+1}$  is a state sequence, then

$$\mathbb{P}(X_0 = x_0, X_{t_1} = x_1, \dots, X_{t_n} = x_n) = f(x_0) P_{t_1}(x_0, x_1) P_{t_2 - t_1}(x_1, x_2) \cdots P_{t_n - t_{n-1}}(x_{n-1}, x_n)$$
(16.16.8)

Proof

To simplify the notation, we will just give the cases n = 1 and n = 2, which capture the essence of the proof. First suppose  $x, y \in S$  and  $t \in [0, \infty)$ . Then

$$\mathbb{P}(X_0 = x, X_t = y) = \mathbb{P}(X_0 = x)\mathbb{P}(X_t = y \mid X_0 = x) = f(x)P_t(x, y)$$
(16.16.9)

Next suppose that  $x, \, y, \, z \in S$  and  $s, \, t \in [0,\infty)$  with s < t . Then

$$\mathbb{P}(X_0 = x, X_s = y, X_t = z) = \mathbb{P}(X_t = z \mid X_0 = x, X_s = y) \mathbb{P}(X_0 = x, X_s = y)$$
(16.16.10)

But by the Markov and time homogeneous properties,  $\mathbb{P}(X_t = z \mid X_0 = x, X_s = y) = P_{t-s}(y, z)$ . By the n = 1 case,  $\mathbb{P}(X_0 = x, X_s = y) = f(x)P_s(x, y)$ . Hence

$$\mathbb{P}(X_0 = x, X_s = y, X_t = z) = f(x)P_s(x, y)P_{t-s}(y, z) \tag{16.16.11}$$

As with any matrix on S, the transition matrices define left and right operations on functions which are generalizations of matrix multiplication. For a transition matrix, both have natural interpretations.

Suppose that  $f: S \to \mathbb{R}$ , and that either f is nonnegative or  $f \in \mathscr{B}$ . Then for  $t \in [0, \infty)$ ,

$$P_t f(x) = \sum_{y \in S} P_t(x,y) f(y) = \mathbb{E}[f(X_t) \mid X_0 = x], \quad x \in S$$
 (16.16.12)

The mapping  $f \mapsto P_t f$  is a bounded, linear operator on  $\mathscr{B}$  and  $||P_t|| = 1$ .

Proof

Since  $P_t(x, \cdot)$  is the conditional probability density function of  $X_t$  given  $X_0 = x$ , it follows that  $P_t f(x) = \mathbb{E}[f(X_t) | X_0 = x]$ . The statement about  $f \mapsto P_t f$  follows from general results on probability kernels.

If *f* is nonnegative and *S* is infinite, then it's possible that  $P_t f(x) = \infty$ . In general, the left operation of a positive kernel acts on positive measures on the state space. In the setting here, if  $\mu$  is a positive (Borel) measure on  $(S, \mathscr{S})$ , then the function  $f : S \to [0, \infty)$  given by

 $f(x) = \mu\{x\}$  for  $x \in S$  is the density function of  $\mu$  with respect to counting measure # on  $(S, \mathscr{S})$ . This simply means that  $\mu(A) = \sum_{x \in A} f(x)$  for  $A \subseteq S$ . Conversely, given  $f: S \to [0, \infty)$ , the set function  $\mu(A) = \sum_{x \in A} f(x)$  for  $A \subseteq S$  defines a positive measure on  $(S, \mathscr{S})$  with f as its density function. So for the left operation of  $P_t$ , it's natural to consider only nonnegative functions.

If  $f: S \to [0,\infty)$  then

$$fP_t(y) = \sum_{x \in S} f(x)P_t(x,y), \quad y \in S$$
 (16.16.13)

If  $X_0$  has probability density function f then  $X_t$  has probability density function  $fP_t$ .

Proof

If  $X_0$  has PDF f, then conditioning gives

$$\mathbb{P}(X_t = y) = \sum_{x \in S} \mathbb{P}(X_t = y \mid X_0 = x) \mathbb{P}(X_0 = x) = \sum_{x \in S} P_t(x, y) f(x) = f P_t(x), \quad y \in S \tag{16.16.14}$$

More generally, if f is the density function of a positive measure  $\mu$  on  $(S, \mathscr{S})$  then  $fP_t$  is the density function of the measure  $\mu P_t$ , defined by

$$\mu P_t(A) = \sum_{x \in S} \mu\{x\} P_t(x, A) = \sum_{x \in S} f(x) P_t(x, A), \quad A \subseteq S$$
(16.16.15)

A function  $f: S \to [0, \infty)$  is *invariant* for the Markov chain X (or for the transition semigroup P) if  $fP_t = f$  for every  $t \in [0, \infty)$ .

It follows that if  $X_0$  has an invariant probability density function f, then  $X_t$  has probability density function f for every  $t \in [0, \infty)$ , so X is identically distributed. Invariant and limiting distributions are fundamentally important for continuous-time Markov chains.

#### Standard Semigroups

Suppose again that  $X = \{X_t : t \in [0, \infty)\}$  is a Markov chain on S with transition semigroup  $P = \{P_t : t \in [0, \infty)\}$ . Once again, continuity assumptions need to be imposed on X in order to rule out strange behavior that would otherwise greatly complicate the theory. In terms of the transition semigroup P, here is the basic assumption:

The transition semigroup  $oldsymbol{P}$  is *standard* if  $P_t(x,x) 
ightarrow 1$  as  $t \downarrow 0$  for each  $x \in S$ .

Since  $P_0(x, x) = 1$  for  $x \in S$ , the standard assumption is clearly a continuity assumption. It actually implies much stronger smoothness properties that we will build up by stages.

If the transition semigroup  $P = \{P_t : t \in [0, \infty)\}$  is standard, then the function  $t \mapsto P_t(x, y)$  is right continuous for each  $(x, y) \in S^2$ .

Proof

First note that if  $(x, y) \in S^2$  with  $x \neq y$  then  $P_h(x, y) \leq 1 - P_h(x, x) \rightarrow 0$  as  $h \downarrow 0$ . Hence  $P_h(x, y) \rightarrow I(x, y)$  as  $h \downarrow 0$  for all  $(x, y) \in S^2$ . Suppose next that  $t \in (0, \infty)$  and  $(x, y) \in S^2$ . By the semigroup property,

$$P_{t+h}(x,y) = P_t P_h(x,y) = \sum_{z \in S} P_t(x,z) P_h(z,y)$$
 (16.16.16)

But  $P_h(z,y) o I(z,y)$  as  $h \downarrow 0$  so by the bounded convergence theorem,  $P_{t+h}(x,y) o P_t(x,y)$  as  $h \downarrow 0$ .

Our next result connects one of the basic assumptions in the section on transition times and the embedded chain with the standard assumption here.

If the Markov chain  $\boldsymbol{X}$  has no instantaneous states then the transition semigroup  $\boldsymbol{P}$  is standard.

Proof

Given  $X_0 = x \in S$  note that au > t implies  $X_t = x$  . Hence

 $P_t(x,x) = \mathbb{P}(X_t = x \mid X_0 = x) \ge \mathbb{P}(\tau > t \mid X_0 = x) = e^{-\lambda(x)t}$ (16.16.17)

Since  $m{X}$  has no instantaneous states,  $0 \le \lambda(x) < \infty$  so  $e^{-\lambda(x)t} \to 1$  as  $t \downarrow 0$ .

Recall that the non-existence of instantaneous states is essentially equivalent to the right continuity of X. So we have the nice result that if X is right continuous, then so is P. For the remainder of our discussion, we assume that  $X = \{X_t : t \in [0, \infty)\}$  is a regular Markov chain on S with transition semigroup  $P = \{P_t : t \in [0, \infty)\}$ , exponential function  $\lambda$  and one-step transition matrix Q for the jump chain. Our next result is the fundamental integral equations relating P,  $\lambda$ , and Q.

For 
$$t\in [0,\infty)$$
,

$$P_t(x,y) = I(x,y)e^{-\lambda(x)t} + \int_0^t \lambda(x)e^{-\lambda(x)s}QP_{t-s}(x,y)\,ds, \quad (x,y) \in S^2$$
 (16.16.18)

Proof

If x is an absorbing state, then the equation trivially holds, since  $\lambda(x) = 0$  and  $P_t(x, y) = I(x, y)$ . So suppose that x is a stable state, and as above, let  $\tau = \inf\{t \in [0, \infty) : X_t \neq X_0\}$ . Given  $X_0 = x$ ,  $\tau$  has a proper exponential distribution with parameter  $\lambda(x) \in (0, \infty)$ . Taking cases,

$$P_t(x,y) = \mathbb{P}(X_t = y \mid X_0 = x) = \mathbb{P}(X_t = y, \tau > t \mid X_0 = x) + \mathbb{P}(X_t = y, \tau \le t \mid X_0 = x)$$
(16.16.19)

The first term on the right is 0 if  $y \neq x$  and is  $\mathbb{P}(\tau > t \mid X_0 = x) = e^{-\lambda(x)t}$  if y = x. In short,

$$\mathbb{P}(X_t = y, au > t \mid X_0 = x) = I(x, y)e^{-\lambda(x)s}$$
(16.16.20)

For the second term on the right in the displayed equation, we condition on  $\tau$  and  $Y_1 = X_{\tau}$ . By a result in the last section on transition times and the embedded chain, the joint PDF of  $(\tau, Y_1)$  at  $s \in [0, \infty)$  and  $z \in S$ , given  $X_0 = x$ , is  $\lambda(x)e^{-\lambda(x)s}Q(x, z)$  (continuous in time, discrete in space). Also, given  $\tau = s \in [0, t]$  and  $Y_1 = z \in S$ , we can use the strong Markov property to "restart the clock" at s giving

$$\mathbb{P}(X_t = y \mid X_0 = x, \tau = s, Y_1 = z) = \mathbb{P}(X_{t-s} = y \mid X_0 = z) = P_{t-s}(z, y)$$
(16.16.21)

Putting the pieces together we have

$$\mathbb{P}(X_t = y, \tau \le t \mid X_0 = x) = \int_0^t \lambda(x) e^{-\lambda(x)s} \sum_{z \in S} Q(x, z) P_{t-s}(z, y) \, ds = \int_0^t \lambda(x) e^{-\lambda(x)s} Q P_{t-s}(x, y) \, ds \quad (16.16.22)$$

We can now improve on the continuity result that we got earlier. First recall the leads to relation for the jump chain Y: For  $(x, y) \in S^2$ , x leads to y if  $Q^n(x, y) > 0$  for some  $n \in \mathbb{N}$ . So by definition, x leads to x for each  $x \in S$ , and for  $(x, y) \in S^2$  with  $x \neq y$ , x leads to y if and only if the discrete-time chain starting in x eventually reaches y with positive probability.

For  $(x,y)\in S^2$  ,

1.  $t \mapsto P_t(x, y)$  is continuous.

- 2. If *x* leads to *y* then  $P_t(x, y) > 0$  for every  $t \in (0, \infty)$ .
- 3. If x does not lead to y then  $P_t(x, y) = 0$  for every  $t \in (0, \infty)$ .

Proof

For  $t \in [0, \infty)$ , we can use the change of variables r = t - s in the fundamental integral equation to get

$$P_t(x,y) = I(x,y)e^{-\lambda(x)t} + \lambda(x)e^{-\lambda(x)t} \int_0^t e^{\lambda(x)r} Q P_r(x,y) \, dr, \quad (x,y) \in S^2$$
 (16.16.23)

- 1. In the displayed equation,  $r \mapsto P_r(x, y)$  is right continuous for every  $(x, y) \in S^2$ , and hence by the bounded convergence theorem again, so is  $r \mapsto QP_r(x, y)$ . Since the integrand in the displayed equation is bounded and right continuous, the integral is a continuous function of t. Hence  $t \mapsto P_t(x, y)$  is continuous for  $(x, y) \in S^2$ .
- 2. For  $x \in S$ , note that  $P_t(x, x) \ge e^{-\lambda(x)t} > 0$  for  $t \in [0, \infty)$ . If x leads to y and  $x \ne y$  then there exists  $n \in \mathbb{N}_+$  and  $(x_1, x_2, \ldots, x_{n-1}) \in S^{n-1}$  such that  $Q(x, x_1) > 0, \ldots Q(x_{n-1}, y) > 0$ . Then

$$P_t(x,y) = \mathbb{P}(X_t = y \mid X_0 = x) \ge \mathbb{P}(Y_1 = x_1, \dots, Y_{n-1} = x_{n-1}, Y_n = y, \tau_n \le t < \tau_{n+1}) > 0$$
(16.16.24)

3. This is clear from the definition of the embedded chain Y.

Parts (b) and (c) are known as the *Lévy dichotomy*, named for Paul Lévy. It's possible to prove the Lévy dichotomy just from the semigroup property of *P*, but this proof is considerably more complicated. In light of the dichotomy, the *leads to* relation clearly makes

sense for the continuous-time chain X as well as the discrete-time embedded chain Y.

#### The Generator Matrix

#### **Definition and Basic Properties**

In this discussion, we assume again that  $X = \{X_t : t \in [0, \infty)\}$  is a regular Markov chain on S with transition semigroup  $P = \{P_t : t \in [0, \infty)\}$ , exponential parameter function  $\lambda$  and one-step transition matrix Q for the embedded jump chain. The fundamental integral equation above now implies that the transition probability matrix  $P_t$  is differentiable in t. The derivative at 0 is particularly important.

The matrix function  $t \mapsto P_t$  has a (right) derivative at 0:

$$\frac{P_t - I}{t} \to G \text{ as } t \downarrow 0 \tag{16.16.25}$$

where the *infinitesimal generator matrix* G is given by  $G(x,y) = -\lambda(x)I(x,y) + \lambda(x)Q(x,y)$  for  $(x,y) \in S^2$ .

Proof

As before the change of variables r = t - s in the fundamental integral equation gives

$$P_t(x,y) = I(x,y)e^{-\lambda(x)t} + \lambda(x)e^{-\lambda(x)t} \int_0^t e^{\lambda(x)r} Q P_r(x,y) dr$$
(16.16.26)

The first term is clearly differentiable in t, and the second term is also differentiable in t since we now know that the integrand is a continuous function of r. The result then follows from standard calculus.

Note that  $\lambda(x)Q(x, x) = 0$  for every  $x \in S$ , since  $\lambda(x) = 0$  is x is absorbing, while Q(x, x) = 0 if x is stable. So  $G(x, x) = -\lambda(x)$  for  $x \in S$ , and  $G(x, y) = \lambda(x)Q(x, y)$  for  $(x, y) \in S^2$  with  $y \neq x$ . Thus, the generator matrix G determines the exponential parameter function  $\lambda$  and the jump transition matrix Q, and thus determines the distribution of the Markov chain X.

Given the generator matrix G of X,

1.  $\lambda(x)=-G(x,x)$  for  $x\in S$ 2. Q(x,y)=-G(x,y)/G(x,x) if  $x\in S$  is stable and  $y\in S-\{x\}$ 

The infinitesimal generator has a nice interpretation in terms of our discussion in the last section. Recall that when the chain first enters a stable state x, we set independent, exponentially distributed "timers" on (x, y), for each  $y \in S - \{x\}$ . Note that G(x, y) is the exponential parameter for the timer on (x, y). As soon as an alarm sounds for a particular (x, y), the chain moves to state y and the process continues.

The generator matrix *G* satisfies the following properties for every  $x \in S$ :

1.  $G(x,x) \leq 0$ 2.  $\sum_{y \in S} G(x,y) = 0$ 

The matrix function  $t \mapsto P_t$  is differentiable on  $[0, \infty)$ , and satisfies the *Kolmogorov backward equation*:  $P'_t = GP_t$ . Explicitly,

$$P_t'(x,y) = -\lambda(x)P_t(x,y) + \sum_{z \in S} \lambda(x)Q(x,z)P_t(z,y), \quad (x,y) \in S^2$$
 (16.16.27)

Proof

The proof is just like before, and follows from standard calculus and the integral equation

$$P_t(x,y) = I(x,y)e^{-\lambda(x)t} + \lambda(x)e^{-\lambda(x)t} \int_0^t e^{\lambda(x)r} QP_r(x,y) dr$$
(16.16.28)

The backward equation is named for Andrei Kolmogorov. In continuous time, the transition semigroup  $P = \{P_t : t \in [0, \infty)\}$  can be obtained from the single, generator matrix G in a way that is reminiscent of the fact that in discrete time, the transition semigroup  $P = \{P^n : n \in \mathbb{N}\}$  can be obtained from the single, one-step matrix P. From a modeling point of view, we often start with the generator matrix G and then solve the the backward equation, subject to the initial condition  $P_0 = I$ , to obtain the semigroup of transition matrices P.

As with any matrix on S, the generator matrix G defines left and right operations on functions that are analogous to ordinary matrix multiplication. The right operation is defined for functions in  $\mathscr{B}$ .

#### If $f \in \mathscr{B}$ then Gf is given by

$$Gf(x)=-\lambda(x)f(x)+\sum_{y\in S}\lambda(x)Q(x,y)f(y),\quad x\in S$$
 $(16.16.29)$ 

Proof

By definition,

$$Gf(x) = \sum_{y \in S} G(x, y) f(y) = -\lambda(x) f(x) + \sum_{y \in S - \{x\}} \lambda(x) Q(x, y) f(y)$$
 (16.16.30)

In the second term, we can sum over all  $y \in S$  since  $\lambda(x) = 0$  if x is absorbing and Q(x, x) = 0 if x is stable. Note that Gf is well defined since

$$\sum_{y \in S - \{x\}} \lambda(x) Q(x,y) \left| f(x) \right| \le \sum_{y \in S - \{x\}} \lambda(x) Q(x,y) \|f\| = \lambda(x) \|f\| \tag{16.16.31}$$

But note that Gf is not in  $\mathscr{B}$  unless  $\lambda \in \mathscr{B}$ . Without this additional assumption, G is a linear operator from the vector space  $\mathscr{B}$  of bounded functions from S to  $\mathbb{R}$  into the vector space of *all* functions from S to  $\mathbb{R}$ . We will return to this point in our next discussion.

#### **Uniform Transition Semigroups**

We can obtain stronger results for the generator matrix if we impose stronger continuity assumptions on *P*.

The transition semigroup  $P = \{P_t : t \in [0, \infty)\}$  is *uniform* if  $P_t(x, x) \rightarrow 1$  as  $t \downarrow 0$  uniformly in  $x \in S$ .

If  $\boldsymbol{P}$  is uniform, then the operator function  $t \mapsto P_t$  is continuous on the vector space  $\mathscr{B}$ .

Proof

The statement means that for  $f \in \mathscr{B}$ , the function  $t \mapsto P_t f$  is continuous with respect to the supremum norm on  $\mathscr{B}$ .

As usual, we want to look at this new assumption from different points of view.

The following are equivalent:

- 1. The transition semigroup  $\boldsymbol{P}$  is uniform.
- 2. The exponential parameter function  $\lambda$  is bounded.
- 3. The generator matrix *G* defiens a bounded linear operator on  $\mathscr{B}$ .

#### Proof

From our remarks above we know that  $\lambda \in \mathscr{B}$  if and only if the generator matrix *G* defines a bounded linear operator on  $\mathscr{B}$ . So we just need to show the equivalence of (a) and (b). If  $\lambda \in \mathscr{B}$  then

$$P_t(x,x) = \mathbb{P}(X_t = x \mid X_0 = x) \ge \mathbb{P}(\tau > t \mid X_0 = x) = \exp[-\lambda(x)t] \ge \exp(-\|\lambda\|t)$$
 (16.16.32)

The last term converges to 1 as  $t \downarrow 0$  uniformly in x.

So when the equivalent conditions are satisfied, the Markov chain  $X = \{X_t : t \in [0, \infty)\}$  is also said to be uniform. As we will see in a later section, a uniform, continuous-time Markov chain can be constructed from a discrete-time Markov chain and an independent Poisson process. For a uniform transition semigroup, we have a companion to the backward equation.

Suppose that P is a uniform transition semigroup. Then  $t \mapsto P_t$  satisfies the Kolmogorov forward equation  $P'_t = P_t G$ . Explicitly,

$$P_t'(x,y) = -\lambda(y)P_t(x,y) + \sum_{z \in S} P_t(x,z)\lambda(z)Q(z,y), \quad (x,y) \in S^2$$
 (16.16.33)

The backward equation holds with more generality than the forward equation, since we only need the transition semigroup P to be *standard* rather than *uniform*. It would seem that we need stronger conditions on  $\lambda$  for the forward equation to hold, for otherwise it's not even obvious that  $\sum_{z \in S} P_t(x, z)\lambda(z)Q(z, y)$  is finite for  $(x, y) \in S$ . On the other hand, the forward equation is sometimes easier to

solve than the backward equation, and the assumption that  $\lambda$  is bounded is met in many applications (and of course holds automatically if *S* is finite).

As a simple corollary, the transition matrices and the generator matrix commute for a uniform semigroup:  $P_t G = GP_t$  for  $t \in [0, \infty)$ . The forward and backward equations formally look like the differential equations for the exponential function. This actually holds with the operator exponential.

Suppose again that  $\mathbf{P} = \{P_t : t \in [0, \infty)\}$  is a uniform transition semigroup with generator *G*. Then

$$P_t = e^{tG} = \sum_{n=0}^{\infty} \frac{t^n}{n!} G^n, \quad t \in [0,\infty)$$
 (16.16.34)

Proof

First  $e^{tG}$  is well defined as a bounded linear operator on  $\mathscr{B}$  for  $t \in [0, \infty)$  (and hence also simply as a matrix), since G is a bounded linear operator on  $\mathscr{B}$ . Trivially  $e^{0G} = I$ , and by basic properties of the matrix exponential,

$$\frac{d}{dt}e^{tG} = Ge^{tG}, \quad t \in (0,\infty)$$
 (16.16.35)

It follows that  $P_t=e^{tG}\;\; ext{for}\;t\in[0,\infty).$ 

We can characterize the generators of uniform transition semigroups. We just need the minimal conditions that the diagonal entries are nonpositive and the row sums are 0.

Suppose that *G* a matrix on *S* with  $||G|| < \infty$ . Then *G* is the generator of a uniform transition semigroup  $P = \{P_t : t \in [0, \infty)\}$  if and only if for every  $x \in S$ ,

1. 
$$G(x,x) \leq 0$$
  
2.  $\sum_{y \in S} G(x,y) = 0$ 

#### Proof

We know of course that if G is the generator of a transition semigroup, then conditions (a) and (b) hold. For the converse, we can use the previous result. Let

$$P_t = e^{tG} = \sum_{n=0}^{\infty} \frac{t^n}{n!} G^n, \quad t \in [0,\infty)$$
 (16.16.36)

which makes sense since G is bounded in norm. Then  $P_t(x, y) \ge 0$  for  $(x, y) \in S^2$ . By part (b),  $\sum_{y \in S} G^n(x, y) = 0$  for every  $x \in S$  and  $n \in \mathbb{N}_+$ , and hence  $\sum_{y \in S} P_t(x, y) = \sum_{y \in S} I(x, y) = 1$  for  $x \in S$ . Finally, the semigroup property is a consequence of the law of exponents, which holds for the exponential of a matrix.

$$P_s P_t = e^{sG} e^{tG} = e^{(s+t)G} = P_{s+t}$$
(16.16.37)

#### **Examples and Exercises**

#### The Two-State Chain

Let  $X = \{X_t : t \in [0, \infty)\}$  be the Markov chain on the set of states  $S = \{0, 1\}$ , with transition rate  $a \in [0, \infty)$  from 0 to 1 and transition rate  $b \in [0, \infty)$  from 1 to 0. This *two-state Markov chain* was studied in the previous section. To avoid the trivial case with both states absorbing, we will assume that a + b > 0.

The generator matrix is

$$G = \begin{bmatrix} -a & a \\ b & -b \end{bmatrix}$$
(16.16.38)

Show that for  $t \in [0, \infty)$ ,

$$P_t = \frac{1}{a+b} \begin{bmatrix} b & a \\ b & a \end{bmatrix} - \frac{1}{a+b} e^{-(a+b)t} \begin{bmatrix} -a & a \\ b & -b \end{bmatrix}$$
(16.16.39)

1. By solving the Kolmogorov backward equation.

2. By solving the Kolmogorov forward equation.

3. By computing  $P_t = e^{tG}$ .

You probably noticed that the forward equation is easier to solve because there is less coupling of terms than in the backward equation.

Define the probability density function f on S by  $f(0) = \frac{b}{a+b}$ ,  $f(1) = \frac{a}{a+b}$ . Show that 1.  $P_t \rightarrow \frac{1}{a+b} \begin{bmatrix} b & a \\ b & a \end{bmatrix}$  as  $t \rightarrow \infty$ , the matrix with f in both rows. 2.  $fP_t = f$  for all  $t \in [0, \infty)$ , so that f is invariant for P. 3. fG = 0.

#### **Computational Exercises**

Consider the Markov chain  $X = \{X_t : t \in [0, \infty)\}$  on  $S = \{0, 1, 2\}$  with exponential parameter function  $\lambda = (4, 1, 3)$  and embedded transition matrix

$$Q = \begin{bmatrix} 0 & \frac{1}{2} & \frac{1}{2} \\ 1 & 0 & 0 \\ \frac{1}{3} & \frac{2}{3} & 0 \end{bmatrix}$$
(16.16.40)

1. Draw the state graph and classify the states.

2. Find the generator matrix G.

3. Find the transition matrix  $P_t$  for  $t \in [0, \infty)$ .

4. Find  $\lim_{t\to\infty} P_t$ .

#### Answer

1. The edge set is  $E = \{(0, 1), (0, 2), (1, 0), (2, 0), (2, 1)\}$  All states are stable.

2. The generator matrix is

$$G = \begin{bmatrix} -4 & 2 & 2\\ 1 & -1 & 0\\ 1 & 2 & -3 \end{bmatrix}$$
(16.16.41)

3. For 
$$t \in [0, \infty)$$
,

$$P_{t} = \frac{1}{15} \begin{bmatrix} 3 + 12e^{-5t} & 10 - 10e^{-3t} & 2 - 12e^{-5t} + 10e^{-3t} \\ 3 - 3e^{-5t} & 10 + 5e^{-3t} & 2 + 3e^{-5t} - 5e^{-3t} \\ 3 - 3e^{-5t} & 10 - 10e^{-3t} & 2 + 3e^{-5t} + 10e^{-3t} \end{bmatrix}$$
(16.16.42)

4.

$$P_t 
ightarrow rac{1}{15} egin{bmatrix} 3 & 10 & 2 \ 3 & 10 & 2 \ 3 & 10 & 2 \ 3 & 10 & 2 \end{bmatrix}$$
(16.16.43)

## **16.17: Potential Matrices**

## **Prelimnaries**

This is the third of the introductory sections on *continuous-time Markov chains*. So our starting point is a time-homogeneous Markov chain  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  defined on an underlying probability space  $(\Omega, \mathscr{F}, \mathbb{P})$  and with discrete state space  $(S, \mathscr{S})$ . Thus S is countable and  $\mathscr{S}$  is the power set of S, so every subset of S is measurable, as is every function from S into another measurable space. In addition, S is given the discret topology so that  $\mathscr{S}$  can also be thought of as the Borel  $\sigma$ -algebra. Every function from S to another topological space is continuous. Counting measure # is the natural measure on  $(S, \mathscr{S})$ , so in the context of the general introduction, integrals over S are simply sums. Also, kernels on S can be thought of as matrices, with rows and sums indexed by S, so the left and right kernel operations are generalizations of matrix multiplication. As before, let  $\mathscr{B}$  denote the collection of bounded functions  $f : S \to \mathbb{R}$ . With the usual pointwise definitions of addition and scalar multiplication,  $\mathscr{B}$  is a vector space. The *supremum norm* on  $\mathscr{B}$  is given by

$$\|f\| = \sup\{|f(x)| : x \in S\}, \quad f \in \mathscr{B}$$

$$(16.17.1)$$

Of course, if *S* is finite,  $\mathscr{B}$  is the set of all real-valued functions on *S*, and  $||f|| = \max\{|f(x)| : x \in S\}$  for  $f \in \mathscr{B}$ . The time space is  $([0, \infty), \mathscr{T})$  where as usual,  $\mathscr{T}$  is the Borel  $\sigma$ -algebra on  $[0, \infty)$  corresponding to the standard Euclidean topology. Lebesgue measure is the natural measure on  $([0, \infty), \mathscr{T})$ .

In our first point of view, we studied X in terms of *when* and *how* the state changes. To review briefly, let  $\tau = \inf\{t \in (0, \infty) : X_t \neq X_0\}$ . Assuming that X is right continuous, the Markov property of X implies the memoryless property of  $\tau$ , and hence the distribution of  $\tau$  given  $X_0 = x$ is exponential with parameter  $\lambda(x) \in [0, \infty)$  for each  $x \in S$ . The assumption of right continuity rules out the pathological possibility that  $\lambda(x) = \infty$ , which would mean that x is an *instantaneous state* so that  $\mathbb{P}(\tau = 0 \mid X_0 = x) = 1$ . On the other hand, if  $\lambda(x) \in (0, \infty)$  then x is a *stable state*, so that  $\tau$  has a proper exponential distribution given  $X_0 = x$  with  $\mathbb{P}(0 < \tau < \infty \mid X_0 = x) = 1$ . Finally, if  $\lambda(x) = 0$  then x is an *absorbing state*, so that  $\mathbb{P}(\tau = \infty \mid X_0 = x) = 1$ . Next we define a sequence of stopping times: First  $\tau_0 = 0$  and  $\tau_1 = \tau$ . Recursively, if  $\tau_n < \infty$ then  $\tau_n = \inf\{t > \tau_n : X_t \neq X_{\tau_n}\}$ , while if  $\tau_n = \infty$  then  $\tau_{n+1} = \infty$ . With  $M = \sup\{n \in \mathbb{N} : \tau_n < \infty\}$  we define  $Y_n = X_{\tau_n}$  if  $n \in \mathbb{N}$  with  $n \leq M$  and  $Y_n = Y_M$  if  $n \in \mathbb{N}$  with n > M. The sequence  $Y = (Y_0, Y_1, \ldots)$  is a discrete-time Markov chain on S with one-step transition matrix Q given by  $Q(x, y) = \mathbb{P}(X_\tau = y \mid X_0 = x)$  if  $x, y \in S$  with x stable, and Q(x, x) = 1 if  $x \in S$  is absorbing. Assuming that X is *regular*, which means that  $\tau_n \to \infty$  as  $n \to \infty$  with probability 1 (ruling out the *explosion* event of infinitely many transitions in finite time), the structure of X is completely determined by the sequence of stopping times  $\tau = (\tau_0, \tau_1, \ldots)$  and the one-step transition matrix Q of the jump chain.

In our second point of view, we studied X in terms of the collection of *transition matrices*  $P = \{P_t : t \in [0, \infty)\}$ , where for  $t \in [0, \infty)$ ,

$$P_t(x,y) = \mathbb{P}(X_t = y \mid X_0 = x), \quad (x,y) \in S^2$$
(16.17.2)

The Markov and time-homogeneous properties imply the *Chapman-Kolmogorov* equations  $P_sP_t = P_{s+t}$  for  $s, t \in [0, \infty)$ , so that P is a *semigroup* of transition matrices. The semigroup P, along with the initial distribution of  $X_0$ , completely determines the distribution of X. For a regular Markov chain X, the fundamental integral equation connecting the two points of view is

$$P_t(x,y) = I(x,y)e^{-\lambda(x)t} + \int_0^t \lambda(x)e^{-\lambda(x)s}QP_{t-s}(x,y)\,ds, \quad (x,y) \in S^2$$
(16.17.3)

which is obtained by conditioning on  $\tau$  and  $X_{\tau}$ . It then follows that the matrix function  $t \mapsto P_t$  is differentiable, with the derivative satisfying the *Kolmogorov backward equation*  $P'_t = GP_t$  where the *generator matrix* G is given by

$$G(x,y)=-\lambda(x)I(x,y)+\lambda(x)Q(x,y),\quad (x,y)\in S^2$$

$$(16.17.4)$$

If the exponential parameter function  $\lambda$  is bounded, then the transition semigroup P is *uniform*, which leads to stronger results. The generator G is a bounded operator on  $\mathscr{B}$ , the backward equation holds as well as a companion forward equation  $P'_t = P_t G$ , as operators on  $\mathscr{B}$  (so with respect to the supremum norm rather than just pointwise). Finally, we can represent the transition matrix as an exponential:  $P_t = e^{tG}$  for  $t \in [0, \infty)$ .

In this section, we study the Markov chain **X** in terms of a family of matrices known as *potential matrices*. This is the least intuitive of the three points of view, but analytically one of the best approaches. Essentially, the potential matrices are transforms of the transition matrices.

#### **Basic Theory**

We assume again that  $X = \{X_t : t \in [0, \infty)\}$  is a regular Markov chain on S with transition semigroup  $P = \{P_t : t \in [0, \infty)\}$ . Our first discussion closely parallels the general theory, except for simplifications caused by the discrete state space.

#### **Definitions and Properties**

For  $lpha \in [0,\infty)$ , the lpha-potential matrix  $U_lpha$  of  $oldsymbol{X}$  is defined as follows:

$$U_{\alpha}(x,y) = \int_{0}^{\infty} e^{-\alpha t} P_{t}(x,y) dt, \quad (x,y) \in S^{2}$$
(16.17.5)

1. The special case  $U = U_0$  is simply the *potential matrix* of **X**.

2. For  $(x, y) \in S^2$ , U(x, y) is the expected amount of time that **X** spends in *y*, starting at *x*.

3. The family of matrices  $U = \{U_{\alpha} : \alpha \in (0, \infty)\}$  is known as the *reolvent* of X.

#### Proof

Since  $t \mapsto P_t(x, y)$  is continuous,  $U_{\alpha}(x, y)$  makes sense for  $(x, y) \in S^2$ . The interpretation of U(x, y) involves an interchange of integrals:

$$U(x,y) = \int_0^\infty P_t(x,y) \, dt = \int_0^\infty \mathbb{E}[\mathbf{1}(X_t = y) \mid X_0 = x] \, dt = \mathbb{E}\left(\int_0^\infty \mathbf{1}(X_t = y) \, dt \mid X_0 = x\right) \tag{16.17.6}$$

The inside integral is the Lebesgue measure of  $\{t \in [0,\infty) : X_t = y\}$ .

It's quite possible that  $U(x, y) = \infty$  for some  $(x, y) \in S^2$ , and knowing when this is the case is of considerable interest. If  $f : S \to \mathbb{R}$  and  $\alpha \ge 0$ , then giving the right operation in its many forms,

$$egin{aligned} U_lpha f(x) &= \sum_{y\in S} U_lpha(x,y) f(y) = \int_0^\infty e^{-lpha t} P_t f(x) \, dt \ &= \int_0^\infty e^{-lpha t} \sum_{y\in S} P_t(x,y) f(y) = \int_0^\infty e^{-lpha t} \mathbb{E}[f(X_t) \mid X_0 = x] \, dt, \quad x\in S \end{aligned}$$

assuming, as always, that the sums and integrals make sense. This will be the case in particular if f is nonnegative (although  $\infty$  is a possible value), or as we will now see, if  $f \in \mathscr{B}$  and  $\alpha > 0$ .

If lpha>0 , then  $U_lpha(x,S)=rac{1}{lpha}$  for all  $x\in S$  . Proof

For  $x \in S$  ,

$$U_{\alpha}(x,S) = \int_{0}^{\infty} e^{-\alpha t} P_{t}(x,S) \, dt = \int_{0}^{\infty} e^{-\alpha t} \, dt = \frac{1}{\alpha}$$
(16.17.7)

It follows that for  $\alpha \in (0, \infty)$ , the right potential operator  $U_{\alpha}$  is a bounded, linear operator on  $\mathscr{B}$  with  $||U_{\alpha}|| = \frac{1}{\alpha}$ . It also follows that  $\alpha U_{\alpha}$  is a probability matrix. This matrix has a nice interpretation.

If  $\alpha > 0$  then  $\alpha U_{\alpha}(x, \cdot)$  is the conditional probability density function of  $X_T$  given  $X_0 = x$ , where T is independent of X and has the exponential distribution on  $[0, \infty)$  with parameter  $\alpha$ .

Proof

Suppose that  $(x, y) \in S^2$ . The random time *T* has PDF  $f(t) = \alpha e^{-\alpha t}$  for  $t \in [0, \infty)$ . Hence, conditioning on *T* gives

$$\mathbb{P}(X_T = y \mid X_0 = x) = \int_0^\infty \alpha e^{-\alpha t} \mathbb{P}(X_T = y \mid T = t, X_0 = x) dt$$
(16.17.8)

But by the substitution rule and the assumption of independence,

$$\mathbb{P}(X_T = y \mid T = t, X_0 = x) = \mathbb{P}(X_t = y \mid T = t, X_0 = x) = \mathbb{P}(X_t = y \mid X_0 = x) = P_t(x, y)$$
(16.17.9)

Substituting gives

$$\mathbb{P}(X_T = y \mid X_0 = x) = \int_0^\infty \alpha e^{-\alpha t} P_t(x, y) \, dt = \alpha U_\alpha(x, y) \tag{16.17.10}$$

So  $\alpha U_{\alpha}$  is a transition probability matrix, just as  $P_t$  is a transition probability matrix, but corresponding to the *random* time T (with  $\alpha \in (0, \infty)$  as a parameter), rather than the deterministic time  $t \in [0, \infty)$ . The potential matrix can also be interpreted in economic terms. Suppose that we receive money at a rate of one unit per unit time whenever the process X is in a particular state  $y \in S$ . Then U(x, y) is the expected total amount of money that we receive, starting in state  $x \in S$ . But money that we receive later is of less value to us *now* than money that we will receive sconer. Specifically, suppose that one monetary unit at time  $t \in [0, \infty)$  has a present value of  $e^{-\alpha t}$  where  $\alpha \in (0, \infty)$  is the *inflation factor* or *discount factor*. Then  $U_{\alpha}(x, y)$  is the total, expected, discounted amount that we receive, starting in  $x \in S$ . A bit more generally, suppose that  $f \in \mathscr{B}$  and that f(y) is the reward (or cost, depending on the sign) per unit time that we receive when the process is in state  $y \in S$ . Then  $U_{\alpha}f(x)$  is the expected, total, discounted reward, starting in state  $x \in S$ .

$$lpha U_lpha o I$$
 as  $lpha o \infty$  .

Proof

Note first that with a change of variables  $s = \alpha t$  ,

$$\alpha U_{\alpha} = \int_0^\infty \alpha e^{-\alpha t} P_t \, dt = \int_0^\infty e^{-s} P_{s/\alpha} \, ds \tag{16.17.11}$$

But for  $s \in [0, \infty)$ ,  $s/\alpha \to 0$  and hence  $P_{s/\alpha} \to I$  as  $\alpha \to \infty$ . The result then follows from the dominated convergence theorem.

If  $f:S o [0,\infty)$ , then giving the left potential operation in its various forms,

$$egin{aligned} & fU_lpha(y) = \sum_{x\in S} f(x)U_lpha(x,y) = \int_0^\infty e^{-lpha t} fP_t(y)\,dt \ & = \int_0^\infty e^{-lpha t} \left[\sum_{x\in S} f(x)P_t(x,y)
ight] dt = \int_0^\infty e^{-lpha t} \left[\sum_{x\in S} f(x)\mathbb{P}(X_t=y)
ight] dt, \quad y\in S. \end{aligned}$$

In particular, suppose that  $\alpha > 0$  and that f is the probability density function of  $X_0$ . Then  $fP_t$  is the probability density function of  $X_t$  for  $t \in [0, \infty)$ , and hence from the last result,  $\alpha fU_{\alpha}$  is the probability density function of  $X_T$ , where again, T is independent of X and has the exponential distribution on  $[0, \infty)$  with parameter  $\alpha$ . The family of potential kernels gives the same information as the family of transition kernels.

The resolvent  $U = \{U_{\alpha} : \alpha \in (0, \infty)\}$  completely determines the family of transition kernels  $P = \{P_t : t \in (0, \infty)\}$ .

Proof

Note that for  $(x, y) \in S^2$ , the function  $\alpha \mapsto U_{\alpha}(x, y)$  on  $(0, \infty)$  is the Laplace transform of the function  $t \mapsto P_t(x, y)$  on  $[0, \infty)$ . The Laplace transform of a continuous function determines the function uniquely.

Although not as intuitive from a probability view point, the potential matrices are in some ways nicer than the transition matrices because of additional smoothness. In particular, the resolvent  $\{U_{\alpha} : \alpha \in [0, \infty)\}$ , along with the initial distribution, completely determine the finite dimensional distributions of the Markov chain X. The potential matrices commute with the transition matrices and with each other.

Suppose that 
$$\alpha$$
,  $\beta$ ,  $t \in [0, \infty)$ . Then  
1.  $P_t U_{\alpha} = U_{\alpha} P_t = \int_0^{\infty} e^{-\alpha s} P_{s+t} ds$   
2.  $U_{\alpha} U_{\beta} = U_{\beta} U_{\alpha} = \int_0^{\infty} \int_0^{\infty} e^{-\alpha s} e^{-\beta t} P_{s+t} ds dt$ 

Proof

The interchanges of matrix multiplication and integrals below are interchanges of sums and integrals, and are justified since the underlying integrands are nonnegative. The other tool used is the semigroup property of  $P = \{P_t : t \in [0, \infty)\}$ . You may want to write out the proofs explicitly to convince yourself

1. First,

$$U_{\alpha}P_{t} = \left(\int_{0}^{\infty} e^{-\alpha s} P_{s} \, ds\right) P_{t} = \int_{0}^{\infty} e^{-\alpha s} P_{s} P_{t} \, ds = \int_{0}^{\infty} e^{-\alpha s} P_{s+t} \, ds \tag{16.17.12}$$

Similarly

$$P_t U_{\alpha} = P_t \int_0^\infty e^{-\alpha s} P_s \, ds = \int_0^\infty e^{-\alpha s} P_t P_s \, ds = \int_0^\infty e^{-\alpha s} P_{s+t} \, ds \tag{16.17.13}$$

2. First

$$U_{\alpha}U_{\beta} = \left(\int_{0}^{\infty} e^{-\alpha s} P_{s} \, ds\right) \left(\int_{0}^{\infty} e^{-\beta t} P_{t} \, dt\right) = \int_{0}^{\infty} \int_{0}^{\infty} e^{-\alpha s} e^{-\beta t} P_{s} P_{t} \, ds \, dt = \int_{0}^{\infty} \int_{0}^{\infty} e^{-\alpha s} e^{-\beta t} P_{s+t} \, ds \, dt \quad (16.17.14)$$

The other direction is similar.

The equations above are matrix equations, and so hold pointwise. The same identities hold for the right operators on the space  $\mathscr{B}$  under the additional restriction that  $\alpha > 0$  and  $\beta > 0$ . The fundamental equation that relates the potential kernels, known as the *resolvent equation*, is given in the next theorem:

If 
$$\alpha, \ \beta \in [0,\infty)$$
 with  $\alpha \leq \beta$  then  $U_{\alpha} = U_{\beta} + (\beta - \alpha)U_{\alpha}U_{\beta}$ .

Proof

If  $\alpha = \beta$  the equation is trivial, so assume  $\alpha < \beta$ . From the previous result,

$$U_{\alpha}U_{\beta} = \int_{0}^{\infty} \int_{0}^{\infty} e^{-\alpha s} e^{-\beta t} P_{s+t} dt ds$$
 (16.17.15)

The transformation u = s + t, v = s maps  $[0, \infty)^2$  one-to-one onto  $\{(u, v) \in [0, \infty)^2 : u \ge v\}$ . The inverse transformation is s = v, t = u - v with Jacobian -1. Hence we have

$$egin{aligned} U_lpha U_eta &= \int_0^\infty \int_0^u e^{-lpha v} e^{-eta (u-v)} P_u \, dv \, du = \int_0^\infty \left( \int_0^u e^{(eta-lpha) v} dv 
ight) e^{-eta u} P_u \, du \ &= rac{1}{eta-lpha} \int_0^\infty \left[ e^{(eta-lpha) u} - 1 
ight] e^{-eta u} P_u du \ &= rac{1}{eta-lpha} \left( \int_0^\infty e^{-lpha u} P_u \, du - \int_0^\infty e^{-eta u} P_u \, du 
ight) = rac{1}{eta-lpha} (U_lpha - U_eta) \end{aligned}$$

Simplifying gives the result. Note that  $U_{\beta}$  is finite since  $\beta > 0$ , so we don't have to worry about the dreaded indeterminate form  $\infty - \infty$ .

The equation above is a matrix equation, and so holds pointwise. The same identity holds for the right potential operators on the space  $\mathscr{B}$ , under the additional restriction that  $\alpha > 0$ .

#### Connections with the Generator

Once again, assume that  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  is a regular Markov chain on S with transition semigroup  $\mathbf{P} = \{P_t : t \in [0, \infty)\}$ , infinitesimal generator G, resolvent  $\mathbf{U} = \{U_\alpha : \alpha \in (0, \infty)\}$ , exponential parameter function  $\lambda$ , and one-step transition matrix Q for the jump chain. There are fundamental connections between the potential  $U_\alpha$  and the generator matrix G, and hence between  $U_\alpha$  and the function  $\lambda$  and the matrix Q.

If  $lpha\in(0,\infty)$  then  $I+GU_lpha=lpha U_lpha$  . In terms of  $\lambda$  and Q,

$$U_{\alpha}(x,y) = \frac{1}{\alpha + \lambda(x)} I(x,y) + \frac{\lambda(x)}{\alpha + \lambda(x)} Q U_{\alpha}(x,y), \quad (x,y) \in S^2$$
(16.17.16)

Proof 1

First,

$$GU_{\alpha} = G \int_{0}^{\infty} e^{-\alpha t} P_{t} dt = \int_{0}^{\infty} e^{-\alpha t} GP_{t} dt = \int_{0}^{\infty} e^{-\alpha t} P_{t}' dt$$
(16.17.17)

Passing *G* through the integrand is justified since  $GP_t(x, y)$  is a sum with just one negative term for  $(x, y) \in S^2$ . The second identity in the displayed equation follows from the backward equation. Integrating by parts then gives

$$GU_{\alpha} = e^{-\alpha t} P_t \Big|_0^{\infty} + \int_0^{\infty} \alpha e^{-\alpha t} P_t \, dt = -I + \alpha U_{\alpha}$$
(16.17.18)

Proof 2

This proof use the fundamental integral equation relating P,  $\lambda$ , and Q as well as the definition of  $U_{\alpha}$  and interchanges of integrals. The interchange is justified since the integrand is nonnegative. So for  $\alpha \in [0, \infty)$  and  $(x, y) \in S^2$ ,

$$\begin{split} U_{\alpha}(x,y) &= \int_{0}^{\infty} e^{-\alpha t} P_{t}(x,y) \, dt \\ &= \int_{0}^{\infty} e^{-\alpha t} \left[ e^{-\lambda(x)t} I(x,y) + \lambda(x) e^{-\lambda(x)t} \int_{0}^{t} e^{\lambda(x)r} Q P_{r}(x,y) \, dr \right] dt \\ &= I(x,y) \int_{0}^{\infty} e^{-[\alpha+\lambda(x)]t} dt + \lambda(x) \int_{0}^{\infty} \int_{0}^{t} e^{-[\alpha+\lambda(x)]t} e^{\lambda(x)r} Q P_{r}(x,y) \, dr \, dt \\ &= \frac{1}{\alpha+\lambda(x)} I(x,y) + \lambda(x) \int_{0}^{\infty} \int_{r}^{\infty} e^{-[\alpha+\lambda(x)]t} e^{\lambda(x)r} Q P_{r}(x,y) \, dt \, dr \\ &= \frac{1}{\alpha+\lambda(x)} I(x,y) + \frac{\lambda(x)}{\alpha+\lambda(x)} \int_{0}^{\infty} e^{-[\alpha+\lambda(x)]r} e^{\lambda(x)r} Q P_{r}(x,y) \, dr \\ &= \frac{1}{\alpha+\lambda(x)} I(x,y) + \frac{\lambda(x)}{\alpha+\lambda(x)} \int_{0}^{\infty} e^{-\alpha r} Q P_{r}(x,y) \, dr = \frac{1}{\alpha+\lambda(x)} I(x,y) + \frac{\lambda(x)}{\alpha+\lambda(x)} Q U_{\alpha}(x,y) \end{split}$$

Proof 3

Recall that  $\alpha U_{\alpha}(x, y) = \mathbb{P}(X_T = y \mid X_0 = x)$  where *T* is independent of *X* and has the exponential distribution with parameter  $\alpha$ . This proof works by conditioning on whether  $T < \tau_1$  or  $T \ge \tau_1$ :

$$\alpha U_{\alpha}(x,y) = \mathbb{P}(X_T = y \mid X_0 = x, T < \tau_1) \mathbb{P}(T < \tau_1 \mid X_0 = x) + \mathbb{P}(X_T = y \mid X_0 = x, T \ge \tau_1) \mathbb{P}(T \ge \tau_1 \mid X_0 = x)$$
(16.17.19)

But  $X_0 = x$  and  $T < \tau_1$  imply  $X_T = x$  so  $\mathbb{P}(X_T = y \mid X_0 = x, T < \tau_1) = I(x, y)$ . And by a basic property of independent exponential variables that we have seen many times before,

$$\mathbb{P}(T < \tau_1 \mid X_0 = x) = \frac{\alpha}{\alpha + \lambda(x)}$$
(16.17.20)

Next, for the first factor in the second term of the displayed equation, we condition on  $X_{\tau_1}$ :

 $\odot$ 

$$\mathbb{P}(X_T = y \mid X_0 = x, T \ge \tau_1) = \sum_{z \in S} \mathbb{P}(X_T = y \mid X_0 = x, X_{\tau_1} = z, T \ge \tau_1) \mathbb{P}(X_{\tau_1} = z \mid X_0 = x, T \ge \tau_1)$$
(16.17.21)

But by the strong Markov property, given  $X_{\tau_1} = z$ , we can restart the clock at time  $\tau_1$  in state z. Moreover, by the memoryless property and independence, the distribution of  $T - \tau_1$  given  $T \ge \tau_1$  is the same as the distribution of T, mainly exponential with parameter  $\alpha$ . It follows that

$$\mathbb{P}(X_T = y \mid X_0 = x, X_{\tau_1} = z, T \ge \tau_1) = \mathbb{P}(X_T = y \mid X_0 = z) = \alpha U_\alpha(z, y)$$
(16.17.22)

Also,  $X_{ au_1}$  is independent of  $au_1$  and T so

$$\mathbb{P}(X_{\tau_1} = z \mid X_0 = x, T \ge \tau_1) = Q(x, z) \tag{16.17.23}$$

Finally using the basic property of exponential distributions again,

$$\mathbb{P}(T \ge \tau_1 \mid X_0 = x) = \frac{\lambda(x)}{\alpha + \lambda(x)}$$
(16.17.24)

Putting all the pieces together we have

$$\alpha U_{\alpha}(x,y) = \frac{\alpha}{\alpha + \lambda(x)} I(x,y) = \frac{\lambda(x)}{\alpha + \lambda(x)} \sum_{z \in S} Q(x,z) \alpha U_{\alpha}(z,y) = \frac{\alpha}{\alpha + \lambda(x)} I(x,y) + \frac{\lambda(x)}{\alpha + \lambda(x)} Q \alpha U_{\alpha}(x,y) \quad (16.17.25)$$

As before, we can get stronger results if we assume that  $\lambda$  is bounded, or equivalently, the transition semigroup P is uniform.

Suppose that  $\lambda$  is bounded and  $\alpha \in (0, \infty)$ . Then as operators on  $\mathscr{B}$  (and hence also as matrices),

T

1.  $I + GU_{\alpha} = \alpha U_{\alpha}$ 

2.  $I + U_{\alpha}G = \alpha U_{\alpha}$ 

Proof

Since  $\lambda$  is bounded, G is a bounded operator on  $\mathscr{B}$ . The proof of (a) then proceeds as before. For (b) we know from the forward and backward equations that  $GP_t = P_t G$  for  $t \in [0, \infty)$  and hence  $GU_\alpha = U_\alpha G$  for  $\alpha \in (0, \infty)$ .

As matrices, the equation in (a) holds with more generality than the equation in (b), much as the Kolmogorov backward equation holds with more generality than the forward equation. Note that

$$U_{lpha}G(x,y) = \sum_{z \in S} U_{lpha}(x,z)G(z,y) = -\lambda(y)U_{lpha}(x,y) + \sum_{z \in S} U_{lpha}(x,z)\lambda(z)Q(z,y), \quad (x,y) \in S^2$$
(16.17.26)

If  $\lambda$  is unbounded, it's not clear that the second sum is finite.

Suppose that  $\lambda$  is bounded and  $\alpha \in (0, \infty)$ . Then as operators on  $\mathscr{B}$  (and hence also as matrices),

1.  $U_{\alpha} = (\alpha I - G)^{-1}$ 2.  $G = \alpha I - U_{\alpha}^{-1}$ 

Proof

1. This follows immediately from the previous result, since  $U_{\alpha}(\alpha I - G) = I$  and  $(\alpha I - G)U_{\alpha} = I$ 

2. This follows from (a):  $\alpha I - G = U_{\alpha}^{-1}$  so  $G = \alpha I - U_{\alpha}^{-1}$ 

So the potential operator  $U_{\alpha}$  and the generator *G* have a simple, elegant inverse relationship. Of course, these results hold in particular if *S* is finite, so that all of the various matrices really are matrices in the elementary sense.

#### **Examples and Exercises**

#### The Two-State Chain

Let  $X = \{X_t : t \in [0, \infty)\}$  be the Markov chain on the set of states  $S = \{0, 1\}$ , with transition rate  $a \in [0, \infty)$  from 0 to 1 and transition rate  $b \in [0, \infty)$  from 1 to 0. To avoid the trivial case with both states absorbing, we will assume that a + b > 0. The first two results below are a review from the previous two sections.

The transition matrix at time  $t\in [0,\infty)$  is

$$P_t = \frac{1}{a+b} \begin{bmatrix} b & a \\ b & a \end{bmatrix} - \frac{1}{a+b} e^{-(a+b)t} \begin{bmatrix} -a & a \\ b & -b \end{bmatrix}, \quad t \in [0,\infty)$$
(16.17.28)

Now we can find the potential matrix in two ways.

For  $\alpha \in (0, \infty)$ , show that the potential matrix  $U_{\alpha}$  is

$$U_{\alpha} = \frac{1}{\alpha(a+b)} \begin{bmatrix} b & a \\ b & a \end{bmatrix} - \frac{1}{(\alpha+a+b)(a+b)} \begin{bmatrix} -a & a \\ b & -b \end{bmatrix}$$
(16.17.29)

1. From the definition.

2. From the relation  $U_{lpha} = (lpha I - G)^{-1}$  .

#### **Computational Exercises**

Consider the Markov chain  $X = \{X_t : t \in [0, \infty)\}$  on  $S = \{0, 1, 2\}$  with exponential parameter function  $\lambda = (4, 1, 3)$  and jump transition matrix

$$Q = \begin{bmatrix} 0 & \frac{1}{2} & \frac{1}{2} \\ 1 & 0 & 0 \\ \frac{1}{3} & \frac{2}{3} & 0 \end{bmatrix}$$
(16.17.30)

1. Draw the state graph and classify the states.

2. Find the generator matrix G.

3. Find the potential matrix  $U_{\alpha}$  for  $\alpha \in (0, \infty)$ .

Answer

1. The edge set is  $E = \{(0,1), (0,2), (1,0), (2,0), (2,1)\}$  All states are stable.

2. The generator matrix is

$$G = \begin{bmatrix} -4 & 2 & 2\\ 1 & -1 & 0\\ 1 & 2 & -3 \end{bmatrix}$$
(16.17.31)

3. For  $\alpha \in (0,\infty)$ ,

$$U_{\alpha} = (\alpha I - G)^{-1} = \frac{1}{15\alpha + 8\alpha^2 + \alpha^3} \begin{bmatrix} 3 + 4\alpha + \alpha^2 & 10 + 2\alpha & 2 + 2\alpha \\ 3 + \alpha & 10 + 7\alpha + \alpha^2 & 2 \\ 3 + \alpha & 10 + 2\alpha & 2 + 5\alpha + \alpha^2 \end{bmatrix}$$
(16.17.32)

# 16.18: Stationary and Limting Distributions of Continuous-Time Chains

In this section, we study the limiting behavior of continuous-time Markov chains by focusing on two interrelated ideas: invariant (or stationary) distributions and limiting distributions. In some ways, the limiting behavior of continuous-time chains is simpler than the limiting behavior of discrete-time chains, in part because the complications caused by periodicity in the discrete-time case do not occur in the continuous-time case. Nonetheless as we will see, the limiting behavior of a continuous-time chain is closely related to the limiting behavior of the embedded, discrete-time jump chain.

## Review

Once again, our starting point is a time-homogeneous, continuous-time Markov chain  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  defined on an underlying probability space  $(\Omega, \mathscr{F}, \mathbb{P})$  and with discrete state space  $(S, \mathscr{S})$ . By definition, this means that S is countable with the discrete topology, so that  $\mathscr{S}$  is the  $\sigma$ -algebra of all subsets of S.

Let's review what we have so far. We assume that the Markov chain X is *regular*. Among other things, this means that the basic structure of X is determined by the *transition times*  $\tau = (\tau_0, \tau_1, \tau_2, \ldots)$  and the *jump chain*  $Y = (Y_0, Y_1, Y_2, \ldots)$ . First,  $\tau_0 = 0$  and  $\tau_1 = \tau = \inf\{t > 0 : X_t \neq X_0\}$ . The time-homogeneous and Markov properties imply that the distribution of  $\tau$  given  $X_0 = x$  is exponential with parameter  $\lambda(x) \in [0, \infty)$ . Part of regularity is that X is right continuous so that there are no *instantaneous states* where  $\lambda(x) = \infty$ , which would mean  $\mathbb{P}(\tau = 0 \mid X_0 = x) = 1$ . On the other hand,  $\lambda(x) \in (0, \infty)$  means that x is a *stable state* so that  $\tau$  has a proper exponential distribution given  $X_0 = x$ , with  $\mathbb{P}(0 < \tau < \infty \mid X_0 = x) = 1$ . Finally,  $\lambda(x) = 0$  means that x is an absorbing state so that  $\mathbb{P}(\tau = \infty \mid X_0 = x) = 1$ . The remaining transition times are defined recursively:  $\tau_{n+1} = \inf\{t > \tau_n : X_t \neq X_{\tau_n}\}$  if  $\tau_n < \infty$  and  $\tau_{n+1} = \infty$  if  $\tau_n = \infty$ . Another component of regularity is that with probability 1,  $\tau_n \to \infty$  as  $n \to \infty$ , ruling out the *explosion event* of infinitely many jumps in finite time. The jump chain Y is formed by sampling X at the transition times (until the chain is sucked into an absorbing state, if that happens). That is, with  $M = \sup\{n: \tau_n < \infty\}$  and for  $n \in \mathbb{N}$ , we define  $Y_n = X_{\tau_n}$  if  $n \leq M$  and  $Y_n = X_{\tau_M}$  if n > M. Then Y is a discrete-time Markov chain with one-step transition matrix Q given  $Q(x, y) = \mathbb{P}(X_\tau = y \mid X_0 = x)$  if  $(x, y) \in S^2$  with x stable and Q(x, x) = 1 if  $x \in S$  is absorbing.

The transition matrix  $P_t$  at time  $t \in [0, \infty)$  is given by  $P_t(x, y) = \mathbb{P}(X_t = y \mid X_0 = x)$  for  $(x, y) \in S^2$ . The time-homogenous and Markov properties imply that the collection of transition matrices  $P = \{P_t : t \in [0, \infty)\}$  satisfies the *Chapman-Kolmogorov equations*  $P_s P_t = P_{s+t}$  for  $s, t \in [0, \infty)$ , and hence is a *semigroup*. of transition matrices The transition semigroup P and the initial distribution of  $X_0$  determine all of the finite-dimensional distributions of X. Since there are no instantaneous states, P is *standard* which means that  $P_t \to I$  as  $t \downarrow 0$  (as matrices, and so pointwise). The fundamental relationship between P on the one hand, and  $\lambda$  and Q on the other, is

$$P_t(x,y) = I(x,y)e^{-\lambda(x)t} + \int_0^t \lambda(x)e^{-\lambda(x)s}QP_{t-s}(x,y)\,ds, \quad (x,y)\in S^2$$
(16.18.1)

From this, it follows that the matrix function  $t \mapsto P_t$  is differentiable (again, pointwise) and satisfies the Kolmogorov backward equation  $\frac{d}{dt}P_t = GP_t$ , where the *infinitesimal generator matrix* G is given by  $G(x, y) = -\lambda(x)I(x, y) + \lambda(x)Q(x, y)$  for  $(x, y) \in S^2$ . If we impose the stronger assumption that P is *uniform*, which means that  $P_t \to I$  as  $t \downarrow 0$  as operators on  $\mathscr{B}$  (so with respect to the supremum norm), then the backward equation as well as the companion Kolmogorov forward equation  $\frac{d}{dt}P_t == P_t G$  hold as operators on  $\mathscr{B}$ . In addition, we have the matrix exponential representation  $P_t = e^{tG}$  for  $t \in [0, \infty)$ . The uniform assumption is equivalent to the exponential parameter function being bounded.

Finally, for  $\alpha \in [0, \infty)$ , the  $\alpha$  potential matrix  $U_{\alpha}$  of  $\boldsymbol{X}$  is  $U_{\alpha} = \int_{0}^{\infty} e^{-\alpha t} P_{t} dt$ . The resolvent  $\boldsymbol{U} = \{U_{\alpha} : \alpha \in (0, \infty)\}$  is the Laplace transform of  $\boldsymbol{P}$  and hence gives the same information as  $\boldsymbol{P}$ . From this point of view, the time-homogeneous and Markov properties lead to the *resolvent equation*  $U_{\alpha} = U_{\beta} + (\beta - \alpha)U_{\alpha}U_{\beta}$  for  $\alpha, \beta \in (0, \infty)$  with  $\alpha \leq \beta$ . For  $\alpha \in (0, \infty)$ , the  $\alpha$  potential matrix is related to the generator by the fundamental equation  $\alpha U_{\alpha} = I + GU_{\alpha}$ . If  $\boldsymbol{P}$  is uniform, then this equation, as well as the companion  $\alpha U_{\alpha} = I + U_{\alpha}G$  hold as operators on  $\mathscr{B}$ , which leads to  $U_{\alpha} = (\alpha I - G)^{-1}$ .

**Basic Theory** 

## **Relations and Classification**

We start our discussion with relations among states and classifications of states. These are the same ones that we studied for discrete-time chains in our study of recurrence and transience, applied here to the jump chain Y. But as we will see, the relations and classifications make sense for the continuous-time chain X as well. The discussion is complicated slightly when there are absorbing states. Only when X is in an absorbing state can we not interpret the values of Y as the values of X at the transition times (because of course, there are no transitions when  $m{X}$  is in an absorbing state). But  $x\in S$  is absorbing for the continuous-time chain X if and only if x is absorbing for the jump chain Y, so this trivial exception is easily handled.

For  $y \in S$  let  $\rho_y = \inf\{n \in \mathbb{N}_+ : Y_n = y\}$ , the (discrete) hitting time to y for the jump chain Y, where as usual,  $\inf(\emptyset) = \infty$ . That is,  $\rho_y$  is the first positive (discrete) time that Y in in state y. The analogous random time for the continuous-time chain X is  $\tau_{\rho_y}$ , where naturally we take  $\tau_{\infty} = \infty$ . This is the first time that **X** is in state *y*, not counting the possible initial period in *y*. Specifically, suppose  $X_0=x$ . If x
eq y then  $au_{
ho_y}=\inf\{t>0: X_t=y\}$  . If x=y then  $au_{
ho_y}=\inf\{t> au_1: X_t=y\}$  .

Define the *hitting matrix* H by

 $H(x,y)=\mathbb{P}(
ho_u<\infty\mid Y_0=x),\quad (x,y)\in S^2$ (16.18.2)Then  $H(x,y)=\mathbb{P}\left( au_{
ho_y}<\infty\mid X_0=x
ight)\;$  except when x is absorbing and y=x.

So for the continuous-time chain, if  $x \in S$  is stable then H(x, x) is the probability that, starting in x, the chain X returns to x after its initial period in x. If  $x, y \in S$  are distinct, then H(x, y) is simply the probability that X, starting in x, eventually reaches y. It follows that the basic relation among states makes sense for either the continuous-time chain X as well as its jump chain Y.

Define the relation  $\rightarrow$  on  $S^2$  by  $x \rightarrow y$  if x = y or H(x, y) > 0.

The *leads to* relation  $\rightarrow$  is *reflexive* by definition:  $x \rightarrow x$  for every  $x \in S$ . From our previous study of discrete-time chains, we know it's also *transitive*: if  $x \to y$  and  $y \to z$  then  $x \to z$  for  $x, y, z \in S$ . We also know that  $x \to y$  if and only if there is a directed path in the state graph from x to y, if and only if  $Q^n(x,y) > 0$  for some  $n \in \mathbb{N}$ . For the continuous-time transition matrices, we have a stronger result that in turn makes a stronger case that the *leads to* relation is fundamental for  $m{X}$ .

Suppose  $(x, y) \in S^2$ .

 $\begin{array}{l} \text{1. If } x \rightarrow y \text{ then } P_t(x,y) > 0 \text{ for all } t \in (0,\infty). \\ \text{2. If } x \nrightarrow y \text{ then } P_t(x,y) = 0 \text{ for all } t \in (0,\infty). \end{array}$ 

Proof

This result is proved in the section on transition matrices and generators.

This result is known as the *Lévy dichotomy*, and is named for Paul Lévy. Let's recall a couple of other definitions:

Suppose that *A* is a nonempty subset of *S*.

1. *A* is *closed* if  $x \in A$  and  $x \to y$  imply  $y \in A$ .

2. *A* is *irreducible* if *A* is closed and has no proper closed subset.

If *S* is irreducible, we also say that the chain *X* itself is irreducible.

If *A* is a nonempty subset of *S*, then  $cl(A) = \{y \in S : x \to y \text{ for some } x \in A\}$  is the smallest closed set containing *A*, and is called the *closure* of *A*.

Suppose that  $A \subseteq S$  is closed. Then

1.  $P_t^A$ , the restriction of  $P_t$  to  $A \times A$ , is a transition probability matrix on A for every  $t \in [0, \infty)$ . 2. *X* restricted to *A* is a continuous-time Markov chain with transition semigroup  $P^A = \{P_t^A : t \in [0, \infty)\}$ . Proof

# 

- 1. If  $x \in A$  and  $y \notin A$ , then x does not lead to y so in particular  $P_t(x, y) = 0$ . It follows that  $\sum_{y \in A} P_t(x, y) = 1$  for  $x \in A$  so  $P_t^A$  is a transition probability matrix.
- 2. This follows from (a). If the chain starts in *A*, then the chain remains in *A* for all time, and of course, the Markov property still holds.

Define the relation  $\leftrightarrow$  on S by  $x \leftrightarrow y$  if  $x \rightarrow y$  and  $y \rightarrow x$  for  $(x, y) \in S^2$ .

The *to and from* relation  $\leftrightarrow$  defines an equivalence relation on *S* and hence partitions *S* into mutually disjoint equivalence classes. Recall from our study of discrete-time chains that a closed set is not necessarily an equivalence class, nor is an equivalence class necessarily closed. However, an irreducible set is an equivalence class, but an equivalence class may not be irreducible. The importance of the relation  $\leftrightarrow$  stems from the fact that many important properties of Markov chains (in discrete or continuous time) turn out to be *class properties*, shared by all states in an equivalence class. The following definition is fundamental, and once again, makes sense for either the continuous-time chain X or its jump chain Y.

Let  $x \in S$ .

- 1. State *x* is *transient* if H(x, x) < 1
- 2. State *x* is recurrent if H(x, x) = 1.

Recall from our study of discrete-time chains that if *x* is recurrent and  $x \rightarrow y$  then *y* is recurrent and  $y \rightarrow x$ . Thus, recurrence and transience are class properties, shared by all states in an equivalence class.

## Time Spent in a State

For  $x \in S$ , let  $N_x$  denote the number of visits to state x by the jump chain Y, and let  $T_x$  denote the total time spent in state x by the continuous-time chain X. Thus

$$N_x = \sum_{n=0}^{\infty} \mathbf{1}(Y_n = x), \quad T_x = \int_0^{\infty} \mathbf{1}(X_t = x) \, dt \tag{16.18.3}$$

The expected values  $R(x, y) = \mathbb{E}(N_y | Y_0 = x)$  and  $U(x, y) = \mathbb{E}(T_y | X_0 = x)$  for  $(x, y) \in S^2$  define the *potential matrices* of Y and X, respectively. From our previous study of discrete-time chains, we know the distribution and mean of  $N_y$  given  $Y_0 = x$  in terms of the hitting matrix H. The next two results give a review:

Suppose that  $x, y \in S$  are distinct. Then

 $\begin{array}{l} 1. \ \mathbb{P}(N_y = n \mid Y_0 = y) = H^{n-1}(y,y)[1 - H(y,y)] & \text{for } n \in \mathbb{N}_+ \\ 2. \ \mathbb{P}(N_y = 0 \mid Y_0 = x) = 1 - H(x,y) & \text{and } \mathbb{P}(N_y = n \mid Y_0 = x) = H(x,y)H^{n-1}(y,y)[1 - H(y,y)] & \text{for } n \in \mathbb{N}_+ \end{array}$ 

Let's take cases. First suppose that y is recurrent. In part (a),  $\mathbb{P}(N_y = n | Y_0 = y) = 0$  for all  $n \in \mathbb{N}_+$ , and consequently  $\mathbb{P}(N_y = \infty | Y_0 = y) = 1$ . In part (b),  $\mathbb{P}(N_y = n | Y_0 = x) = 0$  for  $n \in \mathbb{N}_+$ , and consequently  $\mathbb{P}(N_y = 0 | Y_0 = x) = 1 - H(x, y)$  while  $\mathbb{P}(N_y = \infty | Y_0 = x) = H(x, y)$ . Suppose next that y is transient. Part (a) specifies a proper geometric distribution on  $\mathbb{N}_+$  while in part (b), probability 1 - H(x, y) is assigned to 0 and the remaining probability H(x, y) is geometrically distributed over  $\mathbb{N}_+$  as in (a). In both cases,  $N_y$  is finite with probability 1. Next we consider the expected value, that is, the (discrete) potential. To state the results succinctly we will use the convention that  $a/0 = \infty$  if a > 0 and 0/0 = 0.

Suppose again that  $x, y \in S$  are distinct. Then

1. R(y, y) = 1/[1 - H(y, y)]2. R(x, y) = H(x, y)/[1 - H(y, y)]

Let's take cases again. If  $y \in S$  is recurrent then  $R(y, y) = \infty$ , and for  $x \in S$  with  $x \neq y$ , either  $R(x, y) = \infty$  if  $x \to y$  or R(x, y) = 0 if  $x \to y$ . If  $y \in S$  is transient, R(y, y) is finite, as is R(x, y) for every  $x \in S$  with  $x \neq y$ . Moreover, there is an inverse relationship of sorts between the potential and the hitting probabilities.

Naturally, our next goal is to find analogous results for the continuous-time chain X. For the distribution of  $T_y$  it's best to use the right distribution function.

Suppose that  $x, y \in S$  are distinct. Then for  $t \in [0, \infty)$ 

$$\begin{array}{l} 1. \ \mathbb{P}(T_y > t \mid X_0 = y) = \exp\{-\lambda(y)[1 - H(y, y)]t\} \\ 2. \ \mathbb{P}(T_y > t \mid X_0 = x) = H(x, y) \exp\{-\lambda(y)[1 - H(y, y)]t\} \end{array}$$

Proof

The proof is by conditioning on  $N_y$ .

1. First, if H(y, y) = 1 (so that y is recurrent), then either y is absorbing with  $\mathbb{P}(\tau_1 = \infty \mid X_0 = y) = 1$  or y is stable and recurrent, so that  $\mathbb{P}(N_y = \infty \mid X_0 = y) = 1$ . In the second case, starting in state  $y, T_y$  is the sum of infinitely many independent variables, each with the exponential distribution with parameter  $\lambda(y) \in (0, \infty)$ . In both cases,  $\mathbb{P}(T_y = \infty \mid X_0 = y) = 1$  and so  $\mathbb{P}(T_y > t \mid X_0 = y) = 1$  for every  $t \in [0, \infty)$ . So suppose that H(y, y) < 1 so that y is transient. Then

$$\mathbb{P}(T_y > t \mid X_0 = y) = \sum_{n=1}^{\infty} \mathbb{P}(T_y > t \mid X_0 = y, N_y = n) \mathbb{P}(N_y = n \mid X_0 = y)$$
(16.18.4)

Given  $N_y = n$ ,  $T_y$  is the sum of n independent variables, each having the exponential distribution with parameter  $\lambda(y)$ . So  $T_y$  has the gamma distribution with parameters n and  $\lambda(y)$  and hence

$$\mathbb{P}(T_y > t \mid X_0 = y, N_y = n) = \sum_{k=0}^{n-1} e^{-\lambda(y)t} \frac{[\lambda(y)t]^k}{k!}$$
(16.18.5)

From the previous result,  $\mathbb{P}(N_y = n \mid X_0 = y) = \mathbb{P}(N_y = n \mid Y_0 = y) = H^{n-1}(y, y)[1 - H(y, y)]$ . We substitute, change the order of summation, use geometric series and then exponential series:

$$egin{aligned} \mathbb{P}(T_y > t \mid X_0 = y) &= \sum_{n=1}^\infty \left( \sum_{k=0}^{n-1} e^{-\lambda(y)t} rac{[\lambda(y)t]^k}{k!} 
ight) H^{n-1}(y,y) [1-H(y,y)] \ &= e^{-\lambda(y)t} [1-H(y,y)] \sum_{k=0}^\infty rac{[\lambda(y)t]^k}{k!} \sum_{n=k+1}^\infty H^{n-1}(y,y) \ &= e^{-\lambda(y)t} \sum_{k=0}^\infty rac{[\lambda(y)t]^k}{k!} H^k(y,y) = e^{-\lambda(y)t} \exp[\lambda(y)H(y,y)t] \end{aligned}$$

Simplifying gives the result.

2. The proof is similar. If H(y, y) = 1 so that y is recurrent, then starting in state x, either  $T_y = 0$  if  $N_y = 0$ , which occurs with probability 1 - H(x, y) or  $T_y = \infty$  if  $N_y = \infty$ , which occurs with probability H(x, y). If H(y, y) < 1 so that y is transient, then the result follows from conditioning on  $N_y$  as in (a), except that  $\mathbb{P}(T_y = 0 \mid X_0 = x) = \mathbb{P}(N_y = 0 \mid Y_0 = x) = 1 - H(x, y)$ .

Let's take cases as before. Suppose first that y is recurrent. In part (a),  $\mathbb{P}(T_y > t \mid X_0 = y) = 1$  for every  $t \in [0, \infty)$  and hence  $\mathbb{P}(T_y = \infty \mid X_0 = y) = 1$ . In part (b),  $\mathbb{P}(T_y > t \mid X_0 = x) = H(x, y)$  for every  $t \in [0, \infty)$  and consequently  $\mathbb{P}(T_y = 0 \mid X_0 = x) = 1 - H(x, y)$  while  $\mathbb{P}(T_y = \infty \mid X_0 = x) = H(x, y)$ . Suppose next that y is transient. From part (a), the distribution of  $T_y$  given  $X_0 = y$  is exponential with parameter  $\lambda(y)[1 - H(y, y)]$ . In part (b), the distribution assigns probability 1 - H(x, y) to 0 while the remaining probability H(x, y) is exponentially distributed over  $(0, \infty)$  as in (a). Taking expected value, we get a very nice relationship between the potential matrix U of the continuous-time chain X and the potential matrix R of the discrete-time jump chain Y:

For every 
$$(x,y) \in S^2$$

$$U(x,y) = \frac{R(x,y)}{\lambda(y)}$$
(16.18.6)

Proof

If *y* is recurrent, then U(x, y) = R(x, y) and the common value is either 0 if H(x, y) = 0 or  $\infty$  if H(x, y) = 1. So suppose that *y* is transient. We can compute the expected value of  $T_y$  by integrating the right distribution function in the previous theorem. In case x = y, we have

$$U(y,y) = \int_0^\infty \exp\{-\lambda(y)[1 - H(y,y)]t\} \, dt = \frac{1}{\lambda(y)[1 - H(y,y)]} = \frac{R(y,y)}{\lambda(y)} \tag{16.18.7}$$

In the case that x and y are distinct,

$$U(x,y) = \int_0^\infty H(x,y) \exp\{-\lambda(y)[1 - H(y,y)]t\} dt = \frac{H(x,y)}{\lambda(y)[1 - H(y,y)]} = \frac{R(x,y)}{\lambda(y)}$$
(16.18.8)

In particular,  $y \in S$  is transient if and only if  $R(x, y) < \infty$  for every  $x \in S$ , if and only if  $U(x, y) < \infty$  for every  $x \in S$ . On the other hand, y is recurrent if and only if  $R(x, y) = U(x, y) = \infty$  if  $x \to y$  and R(x, y) = U(x, y) = 0 if  $x \to y$ .

#### Null and Positive Recurrence

Unlike transience and recurrence, the definitions of null and positive recurrence of a state  $x \in S$  are different for the continuoustime chain X and its jump chain Y. This is because these definitions depend on the *expected* hitting time to x, starting in x, and not just the *finiteness* of this hitting time. For  $x \in S$ , let  $\nu(x) = \mathbb{E}(\rho_x \mid Y_0 = x)$ , the expected (discrete) return time to x starting in x. Recall that x is *positive recurrent* for Y if  $\nu(x) < \infty$  and x is *null recurrent* if x is recurrent but not positive recurrent, so that H(x, x) = 1 but  $\nu(x) = \infty$ . The definitions are similar for X, but using the continuous hitting time  $\tau_{\rho_x}$ .

For  $x \in S$ , let  $\mu(x) = 0$  if x is absorbing and  $\mu(x) = \mathbb{E}(\tau_{\rho_x} \mid X_0 = x)$  if x is stable. So if x is stable,  $\mu(x)$  is the expected return time to x starting in x (after the initial period in x).

- 1. State *x* is *positive recurrent* for *X* if  $\mu(x) < \infty$ .
- 2. State *x* is *null recurrent* for **X** if *x* recurrent but not positive recurrent, so that H(x, x) = 1 but  $\mu(x) = \infty$ .

A state  $x \in S$  can be positive recurrent for X but null recurrent for its jump chain Y or can be null recurrent for X but positive recurrent for Y. But like transience and recurrence, positive and null recurrence are *class properties*, shared by all states in an equivalence class under the *to and from* equivalence relation  $\leftrightarrow$ .

#### **Invariant Functions**

Our next discussion concerns functions that are invariant for the transition matrix Q of the jump chain Y and functions that are invariant for the transition semigroup  $P = \{P_t : t \in [0, \infty)\}$  of the continuous-time chain X. For both discrete-time and continuous-time chains, there is a close relationship between invariant functions and the limiting behavior in time.

First let's recall the definitions. A function  $f: S \to [0, \infty)$  is *invariant* for Q (or for the chain  $\mathbf{Y}$ ) if fQ = f. It then follows that  $fQ^n = f$  for every  $n \in \mathbb{N}$ . In continuous time we must *assume* invariance at each time. That is, a function  $f: S \to [0, \infty)$  is invariant for  $\mathbf{P}$  (or for the chain  $\mathbf{X}$ ) if  $fP_t = f$  for all  $t \in [0, \infty)$ . Our interest is in nonnegative functions, because we can think of such a function as the density function, with respect to counting measure, of a positive measure on S. We are particularly interested in the special case that f is a *probability density function*, so that  $\sum_{x \in S} f(x) = 1$ . If  $Y_0$  has a probability density function f that is invariant for Q, then  $Y_n$  has probability density function f for all  $n \in \mathbb{N}$  and hence  $\mathbf{Y}$  is *stationary*. Similarly, if  $X_0$  has a probability density function f that is invariant for  $\mathbf{P}$  then  $X_t$  has probability density function f for every  $t \in [0, \infty)$  and once again, the chain  $\mathbf{X}$  is *stationary*.

Our first result shows that there is a one-to-one correspondence between invariant functions for Q and zero functions for the generator G.

Suppose  $f: S \to [0,\infty)$ . Then fG = 0 if and only if  $(\lambda f)Q = \lambda f$ , so that  $\lambda f$  is invariant for Q.

Proof

This is a simple consequence of the definition of the generator:

$$fG(y)=\sum_{x\in S}f(x)G(x,y)=-\lambda(y)f(y)+\sum_{x\in S}f(x)\lambda(x)Q(x,y),\quad y\in S$$
 $(16.18.9)$ 

or in functional form,  $fG = -\lambda f + (\lambda f)Q$ 

If our chain X has no absorbing states, then  $f: S \to [0, \infty)$  is invariant for Q if and only if  $(f/\lambda)G = 0$ .

Suppose that  $f: S \to [0, \infty)$ . Then *f* is invariant for **P** if and only if fG = 0.

#### Proof 1

Assume that  $\lambda$  is bounded, so that the transition semigroup P is uniform. Then  $P_t = e^{tG}$  for  $t \in [0, \infty)$ . So if  $f : S \to [0, \infty)$  then

$$fP_t = f(e^{tG}) = f\sum_{n=0}^{\infty} \frac{t^n}{n!} G^n = f + \sum_{n=1}^{\infty} \frac{t^n}{n!} fG^n$$
(16.18.10)

Since f is nonnegative,  $fP_t=f$  if and only if fG=0 (in which case  $fG^n=0$  for every  $n\in\mathbb{N}_+$  ).

Proof 2

Suppose that  $fP_t = f$  for  $t \in [0, \infty)$ . Then  $\frac{d}{dt}(fP_t) = 0$  for  $t \in [0, \infty)$ . But using the Kolmogorov backward equation,  $\frac{d}{dt}(fP_t) = f\frac{d}{dt}P_t = fGP_t = 0$ . Letting t = 0 we conclude that fG = 0. Conversely, if fG = 0 then  $\frac{d}{dt}(fP_t) = f\frac{d}{dt}P_t = fGP_t = 0$  for  $t \in [0, \infty)$ . It follows that  $fP_t$  is constant in  $t \in [0, \infty)$ . Since  $fP_0 = f$  it follows that  $fP_t = f$  for all  $t \in [0, \infty)$ .

So putting the two main results together we see that f is invariant for the continuous-time chain X if and only if  $\lambda f$  is invariant for the jump chain Y. Our next result shows how functions that are invariant for X are related to the resolvent  $U = \{U_{\alpha} : \alpha \in (0, \infty)\}$ . To appreciate the result, recall that for  $\alpha \in (0, \infty)$  the matrix  $\alpha U_{\alpha}$  is a *probability* matrix, and in fact  $\alpha U_{\alpha}(x, \cdot)$  is the conditional probability density function of  $X_T$ , given  $X_0 = x$ , where T is independent of X and has the exponential distribution with parameter  $\alpha$ . So  $\alpha U_{\alpha}$  is a transition matrix just as  $P_t$  is a transition matrix, but corresponding to the exponentially distributed random time T with parameter  $\alpha \in (0, \infty)$  rather than the deterministic time  $t \in [0, \infty)$ .

Suppose that  $f: S \to [0, \infty)$ . If fG = 0 then  $f(\alpha U_{\alpha}) = f$  for  $\alpha \in (0, \infty)$ . Conversely if  $f(\alpha U_{\alpha}) = f$  for  $\alpha \in (0, \infty)$  then fG = 0.

Proof

Recall that  $I+GU_{lpha}=lpha U_{lpha}~~ ext{for}~lpha\in(0,\infty)$  . Hence if  $fG=0~ ext{then}$  then

$$f(\alpha U_{\alpha}) = f + fGU_{\alpha} = f \tag{16.18.11}$$

Conversely, suppose that  $f(\alpha U_{\alpha}) = f$ . Then

$$fGU_{\alpha} = \int_0^\infty e^{-\alpha t} fGP_t dt = 0 \tag{16.18.12}$$

As a function of  $\alpha \in (0, \infty)$ , the integral on the right side is the Laplace transform of the time function  $t \mapsto fGP_t$ . Hence we must have  $fGP_t = 0$  for  $t \in (0, \infty)$ , and letting  $t \downarrow 0$  gives fG = 0.

So extending our summary,  $f : S \to [0, \infty)$  is invariant for the transition semigroup  $P = \{P_t : t \in [0, \infty)\}$  if and only if  $\lambda f$  is invariant for jump transition matrices  $\{Q^n : n \in \mathbb{N}\}$  if and only if fG = 0 if and only if f is invariant for the collection of probability matrices  $\{\alpha U_\alpha : \alpha \in (0, \infty)\}$ . From our knowledge of the theory for discrete-time chains, we now have the following fundamental result:

Suppose that  $\boldsymbol{X}$  is irreducible and recurrent.

1. There exists  $g: S \to (0, \infty)$  that is invariant for **X**.

2. If *f* is invariant for *X*, then f = cg for some constant  $c \in [0, \infty)$ .

Proof

The result is trivial if *S* consists of a single, necessarily absorbing, state. Otherwise, there are no absorbing states, since *X* is irreducible and so  $\lambda(x) > 0$  for  $x \in S$ . From the result above, *f* is invariant for *X* if and only if  $\lambda f$  is invariant for *Y*. But *Y* is also irreducible and recurrent, so we know that there exists a strictly positive function that is invariant for *Y*, and every other function that is invariant for *Y* is a nonnegative multiple of this one. Hence the same is true for *X*.

Invariant functions have a nice interpretation in terms of *occupation times*, an interpretation that parallels the discrete case. The potential gives the expected total time in a state, starting in another state, but here we need to consider the expected time in a state during a *cycle* that starts and ends in another state.

For  $x \in S$ , define the function  $\gamma_x$  by

$$\gamma_x(y) = \mathbb{E}\left( \int_0^{ au_{
ho_x}} \mathbf{1}(X_s = y) \, ds \, \Big| \, X_0 = x 
ight), \quad y \in S$$
 $(16.18.13)$ 

so that  $\gamma_x(y)$  is the expected *occupation time* in state *y* before the first return to *x*, starting in *x*.

Suppose again that  $\boldsymbol{X}$  is irreducible and recurrent. For  $x \in S$ ,

 $egin{aligned} &1.\ \gamma_x:S o(0,\infty)\ &2.\ \gamma_x ext{ is invariant for }oldsymbol{X}\ &3.\ \gamma_x(x)=1/\lambda(x)\ &4.\ \mu(x)=\sum_{y\in S}\gamma_x(y) \end{aligned}$ 

Proof

As is often the case, the proof is based on results that we already have for the embedded jump chain. For  $x \in S$ , define

$$\delta_x(y) = \mathbb{E}\left(\sum_{n=0}^{
ho_x - 1} \mathbf{1}(Y_n = y) \ \Big| \ Y_0 = x
ight), \quad y \in S$$
 $(16.18.14)$ 

so that  $\delta_x(y)$  is the expected number of visits to y before the first return to x, starting in x, for the jump chain  $\mathbf{Y} = (Y_0, Y_1, \ldots)$ . Since  $\mathbf{X}$  is irreducible and recurrent, so is  $\mathbf{Y}$ . From our results in the discrete case we know that

1.  $\delta_x:S
ightarrow(0,\infty)$ 2.  $\delta_x$  is invariant for  $oldsymbol{Y}$ 3.  $\delta_x(x)=1$ 

From our results above, it follows that the function  $y \mapsto \delta_x(y)/\lambda(y)$  satisfies properties (a), (b), and (c) in the theorem. But each visit to y by the jump chain Y has expected length  $1/\lambda(y)$  for the continuous-time chain X. It follows that  $\gamma_x(y) = \delta_x(y)/\lambda(y)$  for  $x, y \in S$ . By definition,  $\gamma_x(y)$  is the expected occupation time in y before the first return to x, starting in x. Hence, summing over  $y \in S$  gives the expected return time to x, starting in x, so (d) holds.

So now we have some additional insight into positive and null recurrence for the continuous-time chain X and the associated jump chain Y. Suppose again that the chains are irreducible and recurrent. There exist  $g: S \to (0, \infty)$  that is invariant for Y, and then  $g/\lambda$  is invariant for X. The invariant functions are unique up to multiplication by positive constants. The jump chain Y is positive recurrent if and only if  $\sum_{x \in S} g(x) < \infty$  while the continuous-time chain X is positive recurrent if and only if  $\sum_{x \in S} g(x) < \infty$ . Note that if  $\lambda$  is bounded (which is equivalent to the transition semigroup P being uniform), then X is positive recurrent if and only if Y is positive recurrent.

Suppose again that  $\boldsymbol{X}$  is irreducible and recurrent.

1. If *X* is null recurrent then *X* does not have an invariant probability density function.

2. If *X* is positive recurrent then *X* has a unique, positive invariant probability density function.

Proof

From the previous result, there exists  $g: S \to (0, \infty)$  that is invariant for X, and every other invariant function is a nonnegative multiple of this one. The function f given by

$$f(y) = rac{g(y)}{\sum_{x \in S} g(x)}, \quad y \in S$$
 (16.18.15)

is uniquely defined (that is, unchanged if we replace g by cg where c > 0).

 $\begin{array}{l} \text{1. If } \sum_{x\in S}g(x)=\infty \ \text{ then }f(y)=0 \text{ for every }y\in S.\\ \text{2. If } \sum_{x\in S}g(x)<\infty \ \text{ then }f(y)>0 \text{ for every }y\in S \text{ and } \sum_{y\in S}f(y)=1. \end{array}$ 

## Limiting Behavior

Our next discussion focuses on the limiting behavior of the transition semigroup  $P = \{P_t : t \in [0, \infty)\}$ . Our first result is a simple corollary of the result above for potentials.

If  $y\in S$  is transient, then  $P_t(x,y) o 0$  as  $t o\infty$  for every  $x\in S.$ 

Proof

This follows from the previous result. If  $y \in S$  is transient, then for any  $x \in S$ ,

$$U(x,y) = \int_0^\infty P_t(x,y) \, dt < \infty$$
 (16.18.16)

and so we must have  $P_t(x,y) o 0$  as  $t o \infty$  .

So we should turn our attention to the recurrent states. The set of recurrent states partitions into equivalent classes under  $\leftrightarrow$ , and each of these classes is irreducible. Hence we can assume without loss of generality that our continuous-time chain  $X = \{X_t : t \in [0, \infty)\}$  is irreducible and recurrent. To avoid trivialities, we will also assume that S has at least two states. Thus, there are no absorbing states and so  $\lambda(x) > 0$  for  $x \in S$ . Here is the main result.

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  is irreducible and recurrent. Then  $f(y) = \lim_{t \to \infty} P_t(x, y)$  exists for each  $y \in S$ , independently of  $x \in S$ . The function f is invariant for X and

$$f(y) = rac{\gamma_x(y)}{\mu(x)}, \quad y \in S$$
 (16.18.17)

1. If **X** is null recurrent then f(y) = 0 for all  $y \in S$ .

2. If  $oldsymbol{X}$  is positive recurrent then f(y) > 0 for all  $y \in S$  and  $\sum_{y \in S} f(y) = 1$  .

Proof sketch

The basic idea is that

$$\lim_{t\to\infty} P_t(x,y) = \lim_{t\to\infty} \frac{1}{t} \int_0^t P_s(x,y) ds \tag{16.18.18}$$

The expression on the right is the limiting proportion of time spent in  $y \in S$ , starting in  $x \in S$ . This proportion is  $\gamma_x(y)/\mu(x)$ , so the results follow from the theorem above.

The limiting function f can be computed in a number of ways. First we find a function  $g: S \to (0, \infty)$  that is invariant for X. We can do this by solving

- $gP_t=g ext{ for } t\in(0,\infty)$
- qG = 0
- $g(\alpha U_{lpha}) = g ext{ for } lpha \in (0,\infty)$
- hQ = h and then  $g = h/\lambda$

The function g is unique up to multiplication by positive constants. If  $\sum_{x \in S} g(x) < \infty$ , then we are in the positive recurrent case and so f is simply g normalized:

$$f(y) = rac{g(y)}{\sum_{x \in S} g(x)}, \quad y \in S$$
 (16.18.19)

The following result is known as the *ergodic theorem* for continuous-time Markov chains. It can also be thought of as a strong law of large numbers for continuous-time Markov chains.

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  is irreducible and positive recurrent, with (unique) invariant probability density function f. If  $h : S \to \mathbb{R}$  then

$$rac{1}{t}\int_0^t h(X_s)ds o \sum_{x\in S} f(x)h(x) ext{ as } t o\infty ext{ (16.18.20)}$$

with probability 1, assuming that the sum on the right converges absolutely.

## Notes

First, let  $x, y \in S$  and let  $h = \mathbf{1}_y$ , the indicator function of y. Then given  $X_0 = x$ ,  $\frac{1}{t} \int_0^t h(X_s) ds$  is the average occupation time in state y, starting in state x, over the time interval [0, t]. In expected value, this is  $\frac{1}{t} \int_0^t P_s(x, y) ds$  which we know converges to f(y) as  $t \to \infty$ , independently of x. So in this special case, the ergodic theorem states that the convergence is with probability 1 also. A general function  $h: S \to \mathbb{R}$  is a linear combination of the indicator functions of the points in S, so the ergodic theorem is plausible.

Note that no assumptions are made about  $X_0$ , so the limit is independent of the initial state. By now, this should come as no surprise. After a long period of time, the Markov chain X "forgets" about the initial state. Note also that  $\sum_{x \in S} f(x)h(x)$  is the expected value of h, thought of as a random variable on S with probability measure defined by f. On the other hand,  $\frac{1}{t} \int_0^t h(X_s) ds$  is the average of the time function  $s \mapsto h(X_s)$  on the interval [0, t]. So the ergodic theorem states that the limiting *time average* on the left is the same as the *spatial average* on the right.

## Applications and Exercises

## The Two-State Chain

The continuous-time, two-state chain has been studied in the last several sections. The following result puts the pieces together and completes the picture.

Consider the continuous-time Markov chain  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  on  $S = \{0, 1\}$  with transition rate  $a \in (0, \infty)$  from 0 to 1 and transition rate  $b \in (0, \infty)$  from 1 to 0. Give each of the following

- 1. The transition matrix  $Q^n$  for  $oldsymbol{Y}$  at  $n \in \mathbb{N}$ .
- 2. The infinitesimal generator G.
- 3. The transition matrix  $P_t$  for  $\boldsymbol{X}$  at  $t \in [0, \infty)$ .
- 4. The invariant probability density function for  $\boldsymbol{Y}$ .
- 5. The invariant probability density function for *X*.
- 6. The limiting behavior of  $Q^n$  as  $n \to \infty$  .
- 7. The limiting behavior of  $P_t$  as  $t \to \infty$ .

### Answer

Note that since the transition rates *a* and *b* are positive, the chain is irreducible.

1. First, 
$$Q = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$$
 and then for  $n \in \mathbb{N}$ ,  $Q^n = Q$  if  $n$  is odd and  $Q^n = I$  if  $n$  is even.  
2.  $G = \begin{bmatrix} -a & a \\ b & -b \end{bmatrix}$ .  
3.  $P_t = \frac{1}{a+b} \begin{bmatrix} b & a \\ b & a \end{bmatrix} - \frac{1}{a+b} e^{-(a+b)t} \begin{bmatrix} -a & a \\ b & -b \end{bmatrix}$  for  $t \in [0, \infty)$ .  
4.  $f_d = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} \end{bmatrix}$   
5.  $f_c = \begin{bmatrix} \frac{b}{a+b} & \frac{a}{a+b} \end{bmatrix}$   
6. As in (a),  $Q^{2n} = I$  and  $Q^{2n+1} = Q$  for  $n \in \mathbb{N}$ . So there are two sub-sequential limits. The jump chain  $\boldsymbol{Y}$  is periodic with period 2.  
7.  $P_t \rightarrow \frac{1}{a+b} \begin{bmatrix} b & a \\ b & a \end{bmatrix}$  as  $t \rightarrow \infty$ . Each row is  $f_c$ .

### **Computational Exercises**

The following continuous-time chain has also been studied in the previous three sections.

Consider the Markov chain  $X = \{X_t : t \in [0, \infty)\}$  on  $S = \{0, 1, 2\}$  with exponential parameter function  $\lambda = (4, 1, 3)$  and jump transition matrix

$$Q = \begin{bmatrix} 0 & \frac{1}{2} & \frac{1}{2} \\ 1 & 0 & 0 \\ \frac{1}{3} & \frac{2}{3} & 0 \end{bmatrix}$$
(16.18.21)

1. Recall the generator matrix G.

- 2. Find the invariant probability density function  $f_d$  for  $\boldsymbol{Y}$  by solving  $f_d Q = f_d$ .
- 3. Find the invariant probability density function  $f_c$  for  $\boldsymbol{X}$  by solving  $f_c G = 0$ .
- 4. Verify that  $\lambda f_c$  is a multiple of  $f_d$ .
- 5. Describe the limiting behavior of  $Q^n$  as  $n \to \infty$  .
- 6. Describe the limiting behavior of  $P_t$  as  $t \to \infty$ .
- 7. Verify the result in (f) by recalling the transition matrix  $P_t$  for X at  $t \in [0, \infty)$ .

#### Answer

$\begin{bmatrix} -4 & 2 & 2 \end{bmatrix}$
1. $G = \begin{bmatrix} 1 & -1 & 0 \end{bmatrix}$
$\begin{bmatrix} 1 & 2 & -3 \end{bmatrix}$
2. $f_d = \frac{1}{14} \begin{bmatrix} 6 & 5 & 3 \end{bmatrix}$
3. $f_c = \frac{1}{15} \begin{bmatrix} 3 & 10 & 2 \end{bmatrix}$
4. $\lambda f_c = rac{1}{15} [ egin{array}{c} 12 & 10 & 6 \end{bmatrix} = rac{28}{15} f_d$
$\begin{bmatrix} 6 & 5 & 3 \end{bmatrix}$
5. $Q^n  o rac{1}{14} igg  egin{array}{c c} 6 & 5 & 3 \end{array} igg   ext{ as } n  o \infty$
$\begin{bmatrix} 6 & 5 & 3 \end{bmatrix}$
$\begin{bmatrix} 3 & 10 & 2 \end{bmatrix}$
6. $P_t  ightarrow rac{1}{15} igg  3$ 10 2 as $t  ightarrow \infty$
$\begin{bmatrix} 3 & 10 & 2 \end{bmatrix}$
iggriggriggriggriggriggriggriggriggrigg
$7. \ P_t = rac{1}{15} \left[ \begin{array}{ccc} 3 - 3e^{-5t} & 10 + 5e^{-3t} & 2 + 3e^{-5t} - 5e^{-3t} \end{array}  ight]  ext{ for } t \in [0,\infty)$
$\left[ \begin{array}{ccc} 3-3e^{-5t} & 10-10e^{-3t} & 2+3e^{-5t}+10e^{-3t} \end{array}  ight]$

# 16.19: Time Reversal in Continuous-Time Chains

Earlier, we studied time reversal of discrete-time Markov chains. In continous time, the issues are basically the same. First, the Markov property stated in the form that the past and future are independent given the present, essentially treats the past and future symmetrically. However, there is a lack of symmetry in the fact that in the usual formulation, we have an *initial* time 0, but not a *terminal* time. If we introduce a terminal time, then we can run the process backwards in time. In this section, we are interested in the following questions:

- Is the new process still Markov?
- If so, how are the various parameters of the reversed Markov chain related to those of the original chain?
- Under what conditions are the forward and backward Markov chains stochastically the same?

Consideration of these questions leads to *reversed chains*, an important and interesting part of the theory of continuous-time Markov chains. As always, we are also interested in the relationship between properties of a continuous-time chain and the corresponding properties of its discrete-time jump chain. In this section we will see that there are simple and elegant connections between the time reversal of a continuous-time chain and the time-reversal of the jump chain.

## **Basic Theory**

## **Reversed Chains**

Our starting point is a (homogeneous) continuous-time Markov chain  $X = \{X_t : t \in [0, \infty)\}$  with (countable ) state space S. We will assume that X is irreducible, so that every state in S leads to every other state, and to avoid trivialities, we will assume that there are at least two states. The irreducibility assumption involves no serious loss of generality since otherwise we could simply restrict our attention to an irreducible equivalence class of states. With our usual notation, we will let  $P = \{P_t : t \in [0, \infty)\}$  denote the semigroup of transition matrices of X and G the infinitesimal generator. Let  $\lambda(x)$  denote the exponential parameter for the holding time in state  $x \in S$  and Q the transition matrix for the discrete-time jump chain  $Y = (Y_0, Y_1, \ldots)$ . Finally, let  $U = \{U_\alpha : \alpha \in [0, \infty)\}$  denote the collection of potential matrices of X. We will assume that the chain X is regular, which gives us the following properties:

- $P_t(x,x) \rightarrow 1$  as  $t \downarrow 0$  for  $x \in S$ .
- There are no instantaneous states, so  $\lambda(x) < \infty$  for  $x \in S$ .
- The transition times  $(\tau_1, \tau_2, \ldots)$  satisfy  $\tau_n \to \infty$  as  $n \to \infty$ .
- We may assume that the chain *X* is right continuous and has left limits.

The assumption of regularity rules out various types of weird behavior that, while mathematically possible, are usually not appropriate in applications. If X is uniform, a stronger assumption than regularity, we have the following additional properties:

- $P_t(x,x) \rightarrow 1$  as  $t \downarrow 0$  uniformly in  $x \in S$ .
- $\lambda$  is bounded.
- $P_t = e^{tG}$  for  $t \in [0,\infty)$ .
- $U_{\alpha} = (\alpha I G)^{-1}$  for  $\alpha \in (0, \infty)$ .

Now let  $h \in (0, \infty)$ . We will think of h as the *terminal time* or *time horizon* so the chains in our first discussion will be defined on the time interval [0, h]. Notationally, we won't bother to indicate the dependence on h, since ultimately the time horizon won't matter. Define  $\hat{X}_t = X_{h-t}$  for  $t \in [0, h]$ . Thus, the process *forward in time* is  $\mathbf{X} = \{X_t : t \in [0, h]\}$  while the process *backwards in time* is

$$\mathbf{\tilde{X}} = \{ X_t : t \in [0,h] \} = \{ X_{h-t} : t \in [0,h] \}$$
(16.19.1)

Similarly let

$$\hat{\mathscr{F}}_t = \sigma\{\hat{X}_s : s \in [0,t]\} = \sigma\{X_{h-s} : s \in [0,t]\} = \sigma\{X_r : r \in [h-t,h]\}, \quad t \in [0,h]$$
(16.19.2)

So  $\hat{\mathscr{F}}_t$  is the  $\sigma$ -algebra of events of the process  $\hat{X}$  up to time t, which of course, is also the  $\sigma$ -algebra of events of X from time h - t forward. Our first result is that the chain reversed in time is still Markov

The process  $\hat{X} = {\hat{X}_t : t \in [0, h]}$  is a Markov chain, but is not time homogeneous in general. For  $s, t \in [0, h]$  with s < t, the transition matrix from s to t is

$$\hat{P}_{s,t}(x,y) = rac{\mathbb{P}(X_{h-t}=y)}{\mathbb{P}(X_{h-s}=x)} P_{t-s}(y,x), \quad (x,y) \in S^2$$
(16.19.3)

Proof

Let  $A\in\hat{\mathscr{F}}_s$  and  $x,\,y\in S.$  Then

$$\begin{split} \mathbb{P}(\hat{X}_t = y \mid \hat{X}_s = x, A) \; &= \; \frac{\mathbb{P}(\hat{X}_t = y, \hat{X}_s = x, A)}{\mathbb{P}(\hat{X}_s = x, A)} = \frac{\mathbb{P}(X_{h-t} = y, X_{h-s} = x, A)}{\mathbb{P}(X_{h-s} = x, A)} \\ &= \; \frac{\mathbb{P}(A \mid X_{h-t} = y, X_{h-s} = x) \mathbb{P}(X_{h-s} = x \mid X_{h-t} = y) \mathbb{P}(X_{h-t} = y)}{\mathbb{P}(A \mid X_{h-s} = x) \mathbb{P}(X_{h-s} = x)} \end{split}$$

But  $A \in \sigma\{X_r : r \in [h-s,h]\}\;$  and  $h-t < h-s\;$  , so by the Markov property for  $oldsymbol{X}$  ,

$$\mathbb{P}(A \mid X_{h-t} = y, X_{h-s} = x) = \mathbb{P}(A \mid X_{h-s} = x)$$
(16.19.4)

By the time homogeneity of X,  $\mathbb{P}(X_{h-s} = x \mid X_{h-t} = y) = P_{t-s}(y, x)$  . Substituting and simplifying gives

$$\mathbb{P}(\hat{X}_{t} = y \mid \hat{X}_{s} = x, A) = \frac{\mathbb{P}(X_{h-t} = y)}{\mathbb{P}(X_{h-s} = x)} P_{t-s}(y, x)$$
(16.19.5)

However, the backwards chain will be time homogeneous if  $X_0$  has an invariant distribution.

Suppose that X is positive recurrent, with (unique) invariant probability density function f. If  $X_0$  has the invariant distribution, then  $\hat{X}$  is a time-homogeneous Markov chain. The transition matrix at time  $t \in [0, \infty)$  (for every terminal time  $h \ge t$ ), is given by

$$\hat{P}_t(x,y) = rac{f(y)}{f(x)} P_t(y,x), \quad (x,y) \in S^2$$
 (16.19.6)

Proof

This follows from the result above. Recall that if  $X_0$  has PDF f, then  $X_{h-t}$  and  $X_{h-s}$  also have PDF f.

The previous result holds in the limit of the terminal time, regardless of the initial distribution.

Suppose again that X is positive recurrent, with (unique) invariant probability density function f. Regardless of the distribution of  $X_0$ ,

$$\mathbb{P}(\hat{X}_{s+t} = y \mid \hat{X}_s = x) \rightarrow \frac{f(y)}{f(x)} P_t(y, x) \text{ as } h \rightarrow \infty$$
(16.19.7)

Proof

This follows from the conditional probability above and our study of the limiting behavior of continuous-time Markov chains. Since X is irreducible and positive recurrent,  $\mathbb{P}(X_{h-s} = x) \to f(x)$  and  $\mathbb{P}(X_{h-t} = y) \to f(y)$  as  $h \to \infty$  for every  $x, y \in S$ .

These three results are motivation for the definition that follows. We can generalize by defining the reversal of an irreducible Markov chain, as long as there is a positive, invariant function. Recall that a positive invariant function defines a positive measure on S, but of course not in general a probability measure.

Suppose that  $g: S \to (0, \infty)$  is invariant for X. The *reversal* of X with respect to g is the Markov chain  $\hat{X} = {\hat{X}_t : t \in [0, \infty)}$  with transition semigroup  $\hat{P}$  defined by

$$\hat{P}_t(x,y) = rac{g(y)}{g(x)} P_t(y,x), \quad (x,y) \in S^2, \; t \in [0,\infty)$$
 (16.19.8)

Justification

We need to show that the definition makes sense, namely that  $\hat{P}$  defines a transition semigroup for a Markov chain  $\hat{X}$  satisfying the same assumptions that we have imposed on X. First let  $t \in [0, \infty)$ . Since g is invariant for X,

$$\sum_{y \in S} \hat{P}_t(x, y) = \frac{1}{g(x)} \sum_{y \in S} g(y) P_t(y, x) = \frac{g(x)}{g(x)} = 1, \quad x \in S$$
(16.19.9)

Hence  $\hat{P}_t$  is a valid transition matrix. Next we show that the Chapman-Kolmogorov equations (the semigroup property) holds. Let  $s, t \in [0, \infty)$  and  $x, z \in S$ . Then

$$egin{aligned} \hat{P}_s \hat{P}_t(x,z) &= \sum_{y \in S} \hat{P}_s(x,y) \hat{P}_t(y,z) = \sum_{y \in S} rac{g(y)}{g(x)} P_s(y,x) rac{g(z)}{g(y)} P_t(z,y) \ &= rac{g(z)}{g(x)} \sum_{y \in S} P_t(z,y) P_s(y,x) = rac{g(z)}{g(x)} P_{s+t}(z,x) = \hat{P}_{s+t}(x,z) \end{aligned}$$

Next note that  $\hat{P}_t(x,x) = P_t(x,x)$  for every  $x \in S$ . Hence  $\hat{P}_t(x,x) \to 1$  as  $t \downarrow 0$  for x, so  $\hat{P}$  is also a standard transition semigroup. Note also that if P is uniform, then so is  $\hat{P}$ . Finally, since X is irreducible,  $P_t(x,y) > 0$  for every  $(x,y) \in S^2$  and  $t \in (0,\infty)$ . Since g is positive, it follows that  $\hat{P}_t(y,x) > 0$  for every  $(x,y) \in S^2$  and  $t \in (0,\infty)$ , and hence  $\hat{X}$  is also irreducible.

Recall that if *g* is a positive invariant function for *X* then so is *cg* for every constant  $c \in (0, \infty)$ . Note that *g* and *cg* generate the same reversed chain. So let's consider the cases:

Suppose again that  $\boldsymbol{X}$  is a Markov chain satisfying the assumptions above.

- 1. If *X* is recurrent, then *X* always has a positive invariant function *g*, unique up to multiplication by positive constants. Hence the reversal of a recurrent chain *X* always exists and is unique, and so we can refer to the reversal of *X* without reference to the invariant function.
- 2. Even better, if *X* is positive recurrent, then there exists a unique invariant probability density function, and the reversal of *X* can be interpreted as the *time* reversal (relative to a time horizon) when *X* has the invariant distribution, as in the motivating result above.
- 3. If *X* is transient, then there may or may not exist a positive invariant function, and if one does exist, it may not be unique (up to multiplication by positive constants). So a transient chain may have no reversals or more than one.

Nonetheless, the general definition is natural, because most of the important properties of the reversed chain follow from the *basic balance equation* relating the transition semigroups P and  $\hat{P}$ , and the invariant function g:

$$g(x) \hat{P}_t(x,y) = g(y) P_t(y,x), \quad (x,y) \in S^2, \ t \in [0,\infty)$$
 (16.19.10)

We will see the balance equation repeated for other objects associated with the Markov chains.

Suppose again that  $g: S \to (0, \infty)$  is invariant for X, and that X is the time reversal of X with respect to g. Then

1. *g* is also invariant for  $\hat{X}$ .

2. **X** is the time reversal of  $\hat{X}$  with respect to *g*.

Proof

1. For  $y \in S$ ,

$$g\hat{P}_t(y) = \sum_{x \in S} g(x)\hat{P}_t(x,y) = \sum_{x \in S} g(y)P_t(y,x) = g(y)\sum_{x \in S} P_t(y,x) = g(y)$$
(16.19.11)

2. This follows from the symmetry of the fundamental equation:  $g(x)\hat{P}_t(x,y) = g(y)P_t(y,x)$  for  $(x,y) \in S^2$  and  $t \in [0,\infty)$ .

In the balance equation for the transition semigroups, it's not really necessary to know a-priori that the function g is invariant, if we know the two transition semigroups.

Suppose that  $g: S \to (0, \infty)$ . Then g is invariant and the Markov chains X and  $\hat{X}$  are time reversals with respect to g if and only if

$$g(x)\hat{P}_t(x,y) = g(y)P_t(y,x), \quad (x,y)\in S^2, \ t\in [0,\infty)$$
 (16.19.12)

#### Proof

All that is left to show is that the balance equation implies that g is invariant. The computation is exactly the same as in the last result:

$$gP_t(x) = \sum_{y \in S} g(y)P_t(y,x) = \sum_{y \in S} g(x)\hat{P}_t(x,y) = g(x)\sum_{y \in S} \hat{P}_t(x,y) = g(x), \quad x \in S \quad (16.19.13)$$

Here is a slightly more complicated (but equivalent) version of the balance equation for the transition probabilities.

Suppose again that  $g: S \to (0, \infty)$ . Then g is invariant and the chains X and  $\hat{X}$  are time reversals with respect to g if and only if

$$g(x_1) \hat{P}_{t_1}(x_1,x_2) \hat{P}_{t_2}(x_2,x_3) \cdots \hat{P}_{t_n}(x_n,x_{n+1}) = g(x_{n+1}) P_{t_n}(x_{n+1},x_n) P_{t_{n-1}}(x_n,x_{n-1}) \cdots P_{t_1}(x_2,x_1) \quad (16.19.14)$$
 for all  $n \in \mathbb{N}_+$  ,  $(t_1,t_2,\ldots,t_n) \in [0,\infty)^n$ , and  $(x_1,x_2,\ldots,x_{n+1}) \in S^{n+1}$ .

Proof

All that is necessary is to show that the basic balance equation implies the balance equation in the theorem. When n = 1, we have the basic balance equation itself:

$$g(x_1)P_{t_1}(x_1, x_2) = g(x_2)P_{t_1}(x_2, x_1)$$
(16.19.15)

For n=2 ,

$$g(x_1)\hat{P}_{t_1}(x_1,x_2)\hat{P}_{t_2}(x_2,x_3) = g(x_2)P_{t_1}(x_2,x_1)\hat{P}_{t_2}(x_2,x_3) = g(x_3)P_{t_2}(x_3,x_2)P_{t_1}(x_2,x_1)$$
(16.19.16)

Continuing in this manner (or using induction) gives the general result.

The balance equation holds for the potenetial matrices.

Suppose again that  $g: S \to (0, \infty)$ . Then g is invariant and the chains X and  $\hat{X}$  are time reversals with respect to g if and only if the potential matrices satisfy

$$g(x)\hat{U}_{lpha}(x,y) = g(y)U_{lpha}(y,x), \quad (x,y) \in S^2, \; lpha \in [0,\infty)$$
 (16.19.17)

Proof

We just need to show that the balance equation for the transition semigroups is equivalent to the balance equation above for the potential matrices. Suppose first  $g(x)\hat{P}_t(x,y) = g(y)P_t(y,x)$  for  $t \in [0,\infty)$  and  $(x,y) \in S^2$ . Then

$$egin{aligned} g(x)\hat{U}_lpha(x,y) &= g(x)\int_0^\infty e^{-lpha t}\hat{P}_t(x,y)dt = \int_0^\infty e^{-lpha t}g(x)\hat{P}_t(x,y)dt \ &= \int_0^\infty e^{-lpha t}g(y)P_t(y,x)dt = g(y)\int_0^\infty e^{-lpha t}P_t(y,x)dt = g(y)U_lpha(y,x) \end{aligned}$$

Conversely, suppose that  $g(x)\hat{U}_{\alpha}(x,y) = g(y)U_{\alpha}(y,x)$  for  $(x,y) \in S^2$  and  $\alpha \in [0,\infty)$ . As above,

$$g(x)\hat{U}_{\alpha}(x,y) = \int_{0}^{\infty} e^{-\alpha t} g(x)\hat{P}_{t}(x,y)dt$$
(16.19.18)

So for fixed  $(x, y) \in S^2$ , the function  $\alpha \mapsto g(x)\hat{U}_{\alpha}(x, y)$  is the Laplace transform of the time function  $t \mapsto g(x)\hat{P}_t(x, y)$ . Similarly,  $\alpha \mapsto g(y)U_{\alpha}(x, y)$  is the Laplace transform of the  $t \mapsto g(y)P_t(x, y)$ . The Laplace transform of a continuous function uniquely determines the function so it follows that  $g(x)\hat{P}_t(x, y) = g(y)P_t(y, x)$  for  $t \in [0, \infty)$  and  $(x, y) \in S^2$ .

As a corollary, continuous-time chains that are time reversals are of the same type.

If X and  $\hat{X}$  are time reversals, then X and  $\hat{X}$  are of the same type: transient, null recurrent, or positive recurrent. Proof

Suppose that X and  $\hat{X}$  are time reversals with respect to the invariant function  $g: S \to (0, \infty)$ . Then from the previous result,  $\hat{U}(x, x) = U(x, x)$  for  $x \in S$ . The chains are transient if the common potential is finite for each  $x \in S$  and recurrent if the potential is infinite for each  $x \in S$ . Suppose that the chains are recurrent. Then g is unique up to multiplication by positive constants and the chains are both positive recurrent if  $\sum_{x \in S} g(x) < \infty$  and both null recurrent if  $\sum_{x \in S} g(x) = \infty$ .

The balance equation extends to the infinitesimal generator matrices.

Suppose again that  $g: S \to (0, \infty)$ . Then g is invariant and the Markov chains X and  $\hat{X}$  are time reversals if and only if the infinitesimal generators satisfy

$$g(x)\hat{G}(x,y)=g(y)G(y,x), \quad (x,y)\in S^2$$
 (16.19.19)

Proof

We need to show that the balance equation for the transition semigroups is equivalent to the balance equation for the generators. Suppose first that  $g(x)\hat{P}_t(x,y) = g(y)P_t(y,x)$  for  $t \in [0,\infty)$  and  $(x,y) \in S^2$ . Taking derivatives with respect to t and using Kolmogorov's backward equation gives  $g(x)\hat{G}\hat{P}_t(x,y) = g(y)GP_t(y,x)$  for  $t \in [0,\infty)$  and  $(x,y) \in S^2$ . Evaluating at t = 0 gives  $g(x)\hat{G}(x,y) = g(y)G(y,x)$ . Conversely, suppose that  $g(x)\hat{G}(x,y) = g(y)G(y,x)$  for  $(x,y) \in S^2$ . Then repeated application (or induction) shows that  $g(x)\hat{G}^n(x,y) = g(y)G^n(y,x)$  for every  $n \in \mathbb{N}$  and  $(x,y) \in S^2$ . If the transition matrices are uniform, we can express them as exponentials of the generators. Hence for  $t \in [0,\infty)$  and  $(x,y) \in S^2$ ,

$$egin{aligned} g(x) \hat{P}_t(x,y) &= g(x) e^{t \hat{G}(x,y)} = g(x) \sum_{n=0}^\infty rac{t^n}{n!} \hat{G}^n(x,y) = \sum_{n=0}^\infty rac{t^n}{n!} g(x) \hat{G}^n(x,y) \ &= \sum_{n=0}^\infty rac{t^n}{n!} g(y) G^n(y,x) = g(y) \sum_{n=0}^\infty rac{t^n}{n!} G^n(y,x) = g(y) e^{t G(y,x)} = g(y) P_t(y,x) \end{aligned}$$

This leads to further results and connections:

Suppose again that  $g: S \to (0, \infty)$ . Then g is invariant and X and  $\hat{X}$  are time reversals with respect to g if and only if

1.  $\hat{X}$  and X have the same exponential parmeter function  $\lambda$ .

2. The jump chains **Y** and  $\hat{\mathbf{Y}}$  are (discrete) time reversals with respect to  $\lambda g$ .

Proof

The exponential parameter functions are related to the generator matrices by  $\lambda(x) = -G(x, x)$  and  $\hat{\lambda}(x) = -\hat{G}(x, x)$  for  $x \in S$ . The transition matrices for the jump chains are related to the generator matrices by  $Q(x, y) = G(x, y)/\lambda(x)$  and  $\hat{Q}(x, y) = \hat{G}(x, y)/\hat{\lambda}(x)$  for  $(x, y) \in S^2$  with  $x \neq y$ . Hence conditions (a) and (b) are equivalent to

$$g(x)G(x,y) = g(y)G(y,x), \quad (x,y) \in S^2$$
(16.19.20)

Recall also from the general theory, that if *g* is invariant for *X* then  $\lambda g$  is invariant for the jump chain *Y*.

In our original discussion of time reversal in the positive recurrent case, we could have argued that the previous results must be true. If we run the positive recurrent chain  $\mathbf{X} = \{X_t : t \in [0, h]\}$  backwards in time to obtain the time reversed chain  $\hat{\mathbf{X}} = \{\hat{X}_t : t \in [0, h]\}$ , then the exponential parameters for  $\hat{\mathbf{X}}$  must the be same as those for  $\mathbf{X}$ , and the jump chain  $\hat{\mathbf{Y}}$  for  $\hat{\mathbf{X}}$  must be the time reversal of the jump chain  $\hat{\mathbf{Y}}$  for  $\hat{\mathbf{X}}$ .

#### **Reversible Chains**

Clearly an interesting special case is when the time reversal of a continuous-time Markov chain is stochastically the same as the original chain. Once again, we assume that we have a regular Markov chain  $X = \{X_t : t \in [0, \infty)\}$  that is irreducible on the state space S, with transition semigroup  $P = \{P_t : t \in [0, \infty)\}$ . As before,  $U = \{U_\alpha : \alpha \in [0, \infty)\}$  denotes the collection of potential matrices, and G the infinitesimal generator. Finally,  $\lambda$  denotes the exponential parameter function,  $Y = \{Y_n : n \in \mathbb{N}\}$  the jump chain, and Q the transition matrix of Y. Here is the definition of reversibility:

Suppose that  $g: S \to (0, \infty)$  is invariant for X. Then X is *reversible* with respect to g if the time reversed chain  $\hat{X} = \{\hat{X}_t : t \in [0, \infty)\}$  also has transition semigroup P. That is,

$$g(x)P_t(x,y)=g(y)P_t(y,x), \quad (x,y)\in S^2, \ t\in [0,\infty)$$
 (16.19.21)

Clearly if X is reversible with respect to g then X is reversible with respect to cg for every  $c \in (0, \infty)$ . So here is another review of the cases:

Suppose that X is a Markov chain satisfying the assumptions above.

- 1. If **X** is recurrent, then there exists an invariant function  $g: S \to (0, \infty)$  that is unique up to multiplication by positive constants. So **X** is either reversible or not, and we do not have to reference the invariant function.
- 2. Even better, if *X* is positive recurrent, then there exists a unique invariant probability density function *f*. Again, *X* is either reversible or not, but if it is, then with the invariant distribution, the chain *X* is stochastically the same, forward in time or backward in time.
- 3. If *X* is transient, then a positive invariant function may or may not exist. If such a function does exist, it may not be unique, up to multiplication by positive constants. So in the transient case, *X* may be reversible with respect to one invariant function but not with respect to others.

The following results are corollaries of the results above for time reversals. First, we don't need to know a priori that the function g is invariant.

Suppose that  $g: S o (0,\infty)$  . Then g is invariant and  $oldsymbol{X}$  is reversible with respect to g if and only if

$$g(x)P_t(x,y) = g(y)P_t(y,x), \quad (x,y) \in S^2, \ t \in [0,\infty)$$
(16.19.22)

Suppose again that  $g:S o (0,\infty)$  . Then g is invariant and old X is reversible with respect to g if and only if

$$g(x_1)P_{t_1}(x_1,x_2)P_{t_2}(x_2,x_3)\cdots P_{t_n}(x_n,x_{n+1}) = g(x_{n+1})P_{t_n}(x_{n+1},x_n)P_{t_{n-1}}(x_n,x_{n-1})\cdots P_{t_1}(x_2,x_1) \quad (16.19.23)$$

for all 
$$n\in\mathbb{N}_+$$
 ,  $(t_1,t_2,\ldots,t_n)\in[0,\infty)^n$  , and  $(x_1,x_2,\ldots,x_{n+1})\in S^{n+1}$ 

Suppose again that  $g: S \to (0, \infty)$ . Then g is invariant and X is reversible with respect to g if and only if

$$g(x)U_{lpha}(x,y) = g(y)U_{lpha}(y,x), \quad (x,y) \in S^2, \; lpha \in [0,\infty)$$
(16.19.24)

Suppose again that  $g: S \to (0, \infty)$ . Then *g* is invariant and **X** is reversible with respect to *g* if and only if

$$g(x)G(x,y)=g(y)G(y,x), \quad (x,y)\in S^2$$
 (16.19.25)

Suppose again that  $g: S \to (0, \infty)$ . Then g is invariant and X is reversible if and only if the jump chain Y is reversible with respect to  $\lambda g$ .

Recall that X is recurrent if and only if the jump chain Y is recurrent. In this case, the invariant functions for X and Y exist and are unique up to positive constants. So in this case, the previous theorem states that X is reversible if and only if Y is reversible. In the positive recurrent case (the most important case), the following theorem gives a condition for reversibility that does not directly reference the invariant distribution. The condition is known as the *Kolmogorov cycle condition*, and is named for Andrei Kolmogorov

Suppose that **X** is positive recurrent. Then **X** is reversible if and only if for every sequence of distinct states  $(x_1, x_2, \ldots, x_n)$ ,

$$G(x_1, x_2)G(x_2, x_3) \cdots G(x_{n-1}, x_n)G(x_n, x_1) = G(x_1, x_n)G(x_n, x_{n-1}) \cdots G(x_3, x_2)G(x_2, x_1)$$
(16.19.26)

Proof

Suppose that X is reversible, and let f denote the invariant PDF of X. Then  $G(x, y) = \frac{f(y)}{f(x)}G(x, y)$  for  $(x, y) \in S^2$ . Substituting gives the Kolmogorov cycle condition. Conversely, suppose that the Kolmogorov cycle condition holds for X. Recall that  $G(x, y) = \lambda(x)Q(x, y)$  for  $(x, y) \in S^2$ . Substituting into the cycle condition for X gives the cycle condition for Y. Hence Y is reversible and therefore so is X.

Note that the Kolmogorov cycle condition states that the transition rate of visiting states  $(x_2, x_3, \ldots, x_n, x_1)$  in sequence, starting in state  $x_1$  is the same as the transition rate of visiting states  $(x_n, x_{n-1}, \ldots, x_2, x_1)$  in sequence, starting in state  $x_1$ . The cycle

condition is also known as the balance equation for cycles.

## Applications and Exercises

### The Two-State Chain

The continuous-time, two-state chain has been studied in our previous sections on continuous-time chains, so naturally we are interested in time reversal.

Consider the continuous-time Markov chain  $X = \{X_t : t \in [0, \infty)\}$  on  $S = \{0, 1\}$  with transition rate  $a \in (0, \infty)$  from 0 to 1 and transition rate  $b \in (0, \infty)$  from 1 to 0. Show that X is reversible

1. Using the transition semigroup  $\boldsymbol{P} = \{P_t : t \in [0,\infty)\}$  .

- 2. Using the resolvent  $oldsymbol{U} = \{U_lpha: lpha \in (0,\infty)\}$  .
- 3. Using the generator matrix G.

Solutions

First note that X is irreducible since a > 0 and b > 0. Since S is finite, X is positive recurrent.

1. Recall that

$$P_{t} = \frac{1}{a+b} \begin{bmatrix} b & a \\ b & a \end{bmatrix} - \frac{1}{a+b} e^{-(a+b)t} \begin{bmatrix} -a & a \\ b & -b \end{bmatrix}, \quad t \in [0,\infty)$$
(16.19.27)

All we have to do is find a positive function g on S with the property that  $g(0)P_t(0,1) = g(1)P_t(1,0)$ . The other conditions are trivially satisfied. Note that g(0) = b, g(1) = a satisfies the property. It follows that g is invariant for X, unique up to multiplication by positive constants, and that X is reversible.

2. Recall that

$$U_{\alpha} = \frac{1}{\alpha(a+b)} \begin{bmatrix} b & a \\ b & a \end{bmatrix} - \frac{1}{(\alpha+a+b)(a+b)} \begin{bmatrix} -a & a \\ b & -b \end{bmatrix}, \quad \alpha \in (0,\infty)$$
(16.19.28)

Again, we just need to find a positive function g on S with the property that  $g(0)U_{\alpha}(0,1) = g(1)U_{\alpha}(1,0)$ . The other conditions are trivially satisfied. The function g in part (a) satisfies, the condition, which of course must be the case.

3. Recall that  $G = \begin{bmatrix} -a & a \\ b & -b \end{bmatrix}$ . Once again, we just need to find a positive function g on S with the property that g(0)G(0,1) = g(1)G(1,0). The function g given in (a) satisfies the condition. Note that this procedure is the easiest of the three.

Of course, the invariant PDF f is f(0) = b/(a+b), f(1) = a/(a+b).

### **Computational Exercises**

The Markov chain in the following exercise has also been studied in previous sections.

Consider the Markov chain  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  on  $S = \{0, 1, 2\}$  with exponential parameter function  $\lambda = (4, 1, 3)$  and jump transition matrix

$$Q = \begin{bmatrix} 0 & \frac{1}{2} & \frac{1}{2} \\ 1 & 0 & 0 \\ \frac{1}{3} & \frac{2}{3} & 0 \end{bmatrix}$$
(16.19.29)

Give each of the following for the time reversed chain X:

1. The state graph.

- 2. The semigroup of transition matrices  $\hat{\boldsymbol{P}} = \{\hat{P}_t : t \in [0,\infty)\}$  .
- 3. The resolvent of potential matrices  $\hat{m{U}}=\{\hat{U}_{lpha}: lpha\in(0,\infty)\}$  .
- 4. The generator matrix  $\hat{G}$ .
- 5. The transition matrix of the jump chain  $\hat{Y}$ .

## Solutions

Note that the chain is irreducible, and since *S* is finite, positive recurrent. We found previously that an invariant function (unique up to multiplication by positive constants) is g = (3, 10, 2).

- 1. The edge set is  $\hat{E} = \{(1, 0), (2, 0), (0, 1), (0, 2), (1, 2)\}$  The exponential parameter function  $\lambda = (4, 1, 3)$  is the same as for X.
- 2. The transition matrix at  $t\in [0,\infty)$  is

$$\hat{P}_{t} = \frac{1}{15} \begin{bmatrix} 3 + 12e^{-5t} & 10 - 10e^{-5t} & 2 - 2e^{-5t} \\ 3 - 3e^{-3t} & 10 + 5e^{-3t} & 2 - 2e^{-3t} \\ 3 - 18e^{-5t} + 15e^{-3t} & 10 + 15e^{-5t} - 25e^{-3t} & 2 + 3e^{-5t} + 10e^{-3t} \end{bmatrix}$$
(16.19.30)

3. The potential matrix at  $lpha\in(0,\infty)$  is

$$\hat{U}_{\alpha} = \frac{1}{15\alpha + 8\alpha^2 + \alpha^3} \begin{bmatrix} 3 + 4\alpha + \alpha^2 & 10 + \frac{10}{3}\alpha & 2 + \frac{2}{3}\alpha \\ 3 + \frac{3}{5}\alpha & 10 + 7\alpha + \alpha^2 & 2 + \frac{2}{5}\alpha \\ 3 + 3\alpha & 10 & 2 + 5\alpha + \alpha^2 \end{bmatrix}$$
(16.19.31)

4. The generator matrix is

$$\hat{G} = \begin{bmatrix} -4 & \frac{10}{3} & \frac{2}{3} \\ \frac{3}{5} & -1 & \frac{2}{5} \\ 3 & 0 & -3 \end{bmatrix}$$
(16.19.32)

5. The transition matrix of the jump chain is

$$\hat{Q} = \begin{bmatrix} 0 & \frac{5}{6} & \frac{1}{6} \\ \frac{3}{5} & 0 & \frac{2}{5} \\ 1 & 0 & 0 \end{bmatrix}$$
(16.19.33)

# 16.20: Chains Subordinate to the Poisson Process

## Basic Theory

#### Introduction

Recall that the standard Poisson process with rate parameter  $r \in (0, \infty)$  involves three interrelated stochastic processes. First the sequence of *interarrival times*  $\mathbf{T} = (T_1, T_2, ...)$  is independent, and each variable has the exponential distribution with parameter r. Next, the sequence of *arrival times*  $\mathbf{\tau} = (\tau_0, \tau_1, ...)$  is the partial sum sequence associated with the interrival sequence  $\mathbf{T}$ :

$$\tau_n = \sum_{i=1}^n T_i, \quad n \in \mathbb{N}$$
(16.20.1)

For  $n \in \mathbb{N}_+$ , the arrival time  $\tau_n$  has the gamma distribution with parameters n and r. Finally, the Poisson counting process  $N = \{N_t : t \in [0, \infty)\}$  is defined by

$$N_t = \max\{n \in \mathbb{N} : \tau_n \le t\}, \quad t \in [0, \infty) \tag{16.20.2}$$

so that  $N_t$  is the number of arrivals in (0, t] for  $t \in [0, \infty)$ . The counting variable  $N_t$  has the Poisson distribution with parameter rt for  $t \in [0, \infty)$ . The counting process N and the arrival time process  $\tau$  are inverses in the sense that  $\tau_n \leq t$  if and only if  $N_t \geq n$  for  $t \in [0, \infty)$  and  $n \in \mathbb{N}$ . The Poisson counting process can be viewed as a continuous-time Markov chain.

Suppose that  $X_0$  takes values in  $\mathbb{N}$  and is independent of N. Define  $X_t = X_0 + N_t$  for  $t \in [0, \infty)$ . Then  $X = \{X_t : t \in [0, \infty)\}$  is a continuous-time Markov chain on  $\mathbb{N}$  with exponential parameter function given by  $\lambda(x) = r$  for  $x \in \mathbb{N}$  and jump transition matrix Q given by Q(x, x + 1) = 1 for  $x \in S$ .

Proof

This follows directly from the basic structure of a continuous-time Markov chain. Given  $X_t = x$ , the holding time in state  $x \in \mathbb{N}$  is exponential with parameter r, and the next state is deterministically x + 1. Note that the addition of the variable  $X_0$  is just to allow us the freedom of arbitrary initial distributions on the state space, as is routine with Markov processes.

Note that the Poisson process, viewed as a Markov chain is a pure birth chain. Clearly we can generalize this continuous-time Markov chain in a simple way by allowing a general embedded jump chain.

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  is a Markov chain with (countable) state space S, and with constant exponential parameter  $\lambda(x) = r \in (0, \infty)$  for  $x \in S$ , and jump transition matrix Q. Then X is said to be *subordinate* to the Poisson process with rate parameter r.

- 1. The transition times  $(\tau_1, \tau_2, ...)$  are the arrival times of the Poisson process with rate r.
- 2. The inter-transition times  $(\tau_1, \tau_2 \tau_1, ...)$  are the inter-arrival times of the Poisson process with rate r (independent, and each with the exponential distribution with rate r).
- 3.  $N = \{N_t : t \in [0, \infty)\}$  is the Poisson counting process, where  $N_t$  is the number of transitions in (0, t] for  $t \in [0, \infty)$ .
- 4. The Poisson process and the jump chain  $\boldsymbol{Y} = (Y_0, Y_1, \ldots)$  are independent, and  $X_t = Y_{N_t}$  for  $t \in [0, \infty)$ .

#### Proof

These results all follow from the basic structure of a continuous-time Markov chain.

Since all states are stable, note that we must have Q(x, x) = 0 for  $x \in S$ . Note also that for  $x, y \in S$  with  $x \neq y$ , the exponential rate parameter for the transition from x to y is  $\mu(x, y) = rQ(x, y)$ . Conversely suppose that  $\mu : S^2 \to (0, \infty)$  satisfies  $\mu(x, x) = 0$  and  $\sum_{y \in S} \mu(x, y) = r$  for every  $x \in S$ . Then the Markov chain with transition rates given by  $\mu$  is subordinate to the Poisson process with rate r. It's easy to construct a Markov chain subordinate to the Poisson process.

Suppose that  $N = \{N_t : t \in [0, \infty)\}$  is a Poisson counting process with rate  $r \in (0, \infty)$  and that  $Y = \{Y_n : n \in \mathbb{N}\}$  is a discrete-time Markov chain on S, independent of N, whose transition matrix satisfies Q(x, x) = 0 for every  $x \in S$ . Let  $X_t = Y_{N_t}$  for  $t \in [0, \infty)$ . Then  $X = \{X_t : t \in [0, \infty)\}$  is a continuous-time Markov chain subordinate to the Poisson process.

#### Generator and Transition Matrices

Next let's find the generator matrix and the transition semigroup. Suppose again that  $X = \{X_t : t \in [0, \infty)\}$  is a continuous-time Markov chain on S subordinate to the Poisson process with rate  $r \in (0, \infty)$  and with jump transition matrix Q. As usual, let  $P = \{P_t : t \in [0, \infty)\}$  denote the transition semigroup and G the infinitesimal generator.

The generator matrix *G* of *X* is G = r(Q - I). Hence for  $t \in [0, \infty)$ 

1. The Kolmogorov backward equation is  $P'_t = r(Q - I)P_t$ 

2. The Kolmogorov forward equation is  $P'_t = rP_t(Q - I)$ 

Proof

This follows directly from the general theory since  $G(x, x) = -\lambda(x) = -r$  for  $x \in S$  and  $G(x, y) = \lambda(x)Q(x, y) = rQ(x, y)$  for distinct  $x, y \in S$ .

There are several ways to find the transition semigroup  $P = \{P_t : t \in [0, \infty)\}$ . The best way is a probabilistic argument using the underlying Poisson process.

For  $t \in [0, \infty)$ , the transition matrix  $P_t$  is given by

$$P_t = \sum_{n=0}^{\infty} e^{-rt} \frac{(rt)^n}{n!} Q^n$$
(16.20.3)

Proof from the underlying Poisson process

Let  $N_t$  denote the number of transitions in (0, t] for  $t \in [0, \infty)$ , so that  $N = \{N_t : t \in [0, \infty)\}$  is the Poisson counting process. Let  $Y = (Y_0, Y_1, \ldots)$  denote the jump chain, with transition matrix Q. Then N and Y are independent, and  $X_t = Y_{N_t}$  for  $t \in [0, \infty)$ . Conditioning we have

$$egin{aligned} P_t(x,y) &= \mathbb{P}(X_t = y \mid X_0 = x) = \mathbb{P}\left(Y_{N_t} = y \mid Y_0 = x
ight) \ &= \sum_{n=0}^\infty \mathbb{P}\left(Y_{N_t} = y \mid N_t = n, Y_0 = y
ight) \mathbb{P}(N_t = n \mid Y_0 = y) \ &= \sum_{n=0}^\infty \mathbb{P}(Y_n = y \mid Y_0 = x) \mathbb{P}(N_t = n) = \sum_{n=0}^\infty e^{-rt} \, rac{(rt)^n}{n!} Q^n(x,y) \end{aligned}$$

Proof using the generator matrix

Note first that for  $n \in \mathbb{N}$  ,

$$G^{n} = [r(Q-I)]^{n} = r^{n} \sum_{k=0}^{n} \binom{n}{k} (-1)^{n-k} Q^{k}$$
(16.20.4)

Hence

$$\begin{split} P_t &= e^{tG} = \sum_{n=0}^{\infty} \frac{t^n}{n!} G^n = \sum_{n=0}^{\infty} \frac{t^n}{n!} r^n \sum_{k=0}^{\infty} \binom{n}{k} (-1)^{n-k} Q^k \\ &= \sum_{n=0}^{\infty} \sum_{k=0}^n \frac{(rt)^n}{k! (n-k)!} (-1)^{n-k} Q^k = \sum_{k=0}^{\infty} \sum_{n=k}^{\infty} \frac{(rt)^n}{k! (n-k)!} (-1)^{n-k} Q^k \\ &= \sum_{k=0}^{\infty} \frac{(rt)^k}{k!} Q^k \sum_{n=k}^{\infty} \frac{1}{(n-k)!} (-rt)^{n-k} = \sum_{k=0}^{\infty} e^{-rt} \frac{(rt)^k}{k!} Q^k \end{split}$$

#### **Potential Matrices**

Next let's find the potential matrices. As with the transition matrices, we can do this in (at least) two different ways.

Suppose again that  $X = \{X_t : t \in [0, \infty)\}$  is a continuous-time Markov chain on S subordinate to the Poisson process with rate  $r \in (0, \infty)$  and with jump transition matrix Q. For  $\alpha \in (0, \infty)$ , the potential matrix  $U_{\alpha}$  of X is

$$U_{\alpha} = \frac{1}{\alpha + r} \sum_{n=0}^{\infty} \left(\frac{r}{\alpha + r}\right)^n Q^n \tag{16.20.5}$$

Proof from the definition

Using the previous result,

$$egin{aligned} U_lpha(x,y) &= \int_0^\infty e^{-lpha t} P_t(x,y)\,dt = \int_0^\infty e^{-lpha t} \sum_{n=0}^\infty e^{-rt} rac{(rt)^n}{n!} Q^n(x,y)\,dt \ &= \sum_{n=0}^\infty Q^n(x,y) rac{r^n}{n!} \int_0^\infty e^{-(r+lpha)t} t^n dt \end{aligned}$$

The interchange of sum and integral is justified since the terms are nonnegative. Using the change of variables  $s = (r + \alpha)t$  gives

$$U_{\alpha}(x,y) = \frac{1}{\alpha + r} \sum_{n=0}^{\infty} \left(\frac{r}{\alpha + r}\right)^n \frac{1}{n!} Q^n(x,y) \int_0^\infty e^{-st} s^n \, ds \tag{16.20.6}$$

The last integral is n!.

Proof using the generator

From the result above,

$$\alpha I - G = \alpha I - r(Q - I) = (\alpha + r)I - rQ = (\alpha + r)\left(I - \frac{r}{\alpha + r}Q\right)$$
(16.20.7)

Since  $\left\| \frac{r}{\alpha + r} Q \right\| = \frac{r}{\alpha + r} < 1$  we have

$$(\alpha I - G)^{-1} = \frac{1}{\alpha + r} \left( I - \frac{r}{\alpha + r} Q \right)^{-1} = \frac{1}{\alpha + r} \sum_{n=0}^{\infty} \left( \frac{r}{\alpha + r} \right)^n Q^n$$
(16.20.8)

Recall that for  $p \in (0, 1)$ , the *p*-potential matrix of the jump chain  $\mathbf{Y}$  is  $R_p = \sum_{n=0}^{\infty} p^n Q^n$ . Hence we have the following nice relationship between the potential matrix of  $\mathbf{X}$  and the potential matrix of  $\mathbf{Y}$ :

$$U_{\alpha} = \frac{1}{\alpha + r} R_{r/(\alpha + r)} \tag{16.20.9}$$

Next recall that  $\alpha U_{\alpha}(x, \cdot)$  is the probability density function of  $X_T$  given  $X_0 = x$ , where T has the exponential distribution with parameter  $\alpha$  and is independent of X. On the other hand,  $\alpha U_{\alpha}(x, \cdot) = (1-p)R_p(x, \cdot)$  where  $p = r/(\alpha + r)$ . We know from our study of discrete potentials that  $(1-p)R_p(x, \cdot)$  is the probability density function of  $Y_M$  where M has the geometric distribution on  $\mathbb{N}$  with parameter 1-p and is independent of Y. But also  $X_T = Y_{N_T}$ . So it follows that if T has the exponential distribution with parameter  $\alpha$ ,  $N = \{N_t : t \in [0, \infty)\}$  is a Poisson process with rate r, and is independent of T, then  $N_T$  has the geometric distribution on  $\mathbb{N}$  with parameter  $\alpha/(\alpha + r)$ . Of course, we could easily verify this directly, but it's still fun to see such connections.

#### Limiting Behavior and Stationary Distributions

Once again, suppose that  $X = \{X_t : t \in [0, \infty)\}$  is a continuous-time Markov chain on S subordinate to the Poisson process with rate  $r \in (0, \infty)$  and with jump transition matrix Q. Let  $Y = \{Y_n : n \in \mathbb{N}\}$  denote the jump process. The limiting behavior and stationary distributions of X are closely related to those of Y.

Suppose that X (and hence Y) are irreducible and positive recurrent

- 1.  $g: S \to (0, \infty)$  is invariant for **X** if and only if *g* is invariant for **Y**.
- 2. f is an invariant probability density function for X if and only if f is an invariant probability density function for Y.
- 3. *X* is null recurrent if and only if *Y* is null recurrent, and in this case,  $\lim_{n\to\infty} Q^n(x, y) = \lim_{t\to\infty} P_t(x, y) = 0$  for  $(x, y) \in S^2$ .
- 4.  $\boldsymbol{X}$  is positive recurrent if and only if  $\boldsymbol{Y}$  is positive recurrent. If  $\boldsymbol{Y}$  is aperiodic, then

 $\lim_{n \to \infty} Q^n(x,y) = \lim_{t \to \infty} P_t(x,y) = f(y)$  for  $(x,y) \in S^2$ , where f is the invariant probability density function.

#### Proof

All of these results follow from the basic theory of stationary and limiting distributions for continuous-time chains, and the fact that the exponential parameter function  $\lambda$  is constant.

#### **Time Reversal**

Once again, suppose that  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  is a continuous-time Markov chain on S subordinate to the Poisson process with rate  $r \in (0, \infty)$  and with jump transition matrix Q. Let  $\mathbf{Y} = \{Y_n : n \in \mathbb{N}\}$  denote the jump process. We assume that  $\mathbf{X}$  (and hence  $\mathbf{Y}$ ) are irreducible. The time reversal of  $\mathbf{X}$  is closely related to that of  $\mathbf{Y}$ .

Suppose that  $g: S \to (0, \infty)$  is invariant for X. The time reversal  $\hat{X}$  with respect to g is also subordinate to the Poisson process with rate r. The jump chain  $\hat{Y}$  of  $\hat{X}$  is the (discrete) time reversal of Y with respect to g.

Proof

From the previous result, g is also invariant for Y. From the general theory of time reversal, X has the same exponential parameter function as X (namely the constant function r) and so is also subordinate to the Poisson process with rate r. Finally, the jump chain  $\hat{Y}$  of  $\hat{X}$  is the reversal of Y with respect to rg and hence also with respect to g.

In particular, X is reversible with respect to g if and only if Y is reversible with respect to g. As noted earlier, X and Y are of the same type: both transient or both null recurrent or both positive recurrent. In the recurrent case, there exists a positive invariant function that is unique up to multiplication by constants. In this case, the reversal of X is unique, and is the chain subordinate to the Poisson process with rate r whose jump chain is the reversal of Y.

### **Uniform Chains**

In the construction above for a Markov chain  $X = \{X_t : t \in [0, \infty)\}$  that is subordinate to the Poisson process with rate r and jump transition kernel Q, we assumed of course that Q(x, x) = 0 for every  $x \in S$ . So there are no absorbing states and the sequence  $(\tau_1, \tau_2, ...)$  of arrival times of the Poisson process are the jump times of the chain X. However in our introduction to continuous-time chains, we saw that the general construction of a chain starting with the function  $\lambda$  and the transition matrix Q works without this assumption on Q, although the exponential parameters and transition probabilities change. The same idea works here.

Suppose that  $N = \{N_t : t \in [0, \infty)\}$  is a counting Poisson process with rate  $r \in (0, \infty)$  and that  $Y = \{Y_n : n \in \mathbb{N}\}$  is a discrete-time Markov chain with transition matrix Q on  $S \times S$  satisfying Q(x, x) < 1 for  $x \in S$ . Assume also that N and Y are independent. Define  $X_t = Y_{N_t}$  for  $t \in [0, \infty)$ . Then  $X = \{X_t : t \in [0, \infty)\}$  is a continuous-Markov chain with exponential parameter function  $\lambda(x) = r[1 - Q(x, x)]$  for  $x \in S$  and jump transition matrix  $\tilde{Q}$  given by

$$ilde{Q}(x,y) = rac{Q(x,y)}{1-Q(x,x)}, \quad (x,y) \in S^2, \, x 
eq y$$
 (16.20.10)

Proof

This follows from the result in the introduction.

The Markov chain constructed above is no longer a chain subordinate to the Poisson process by our definition above, since the exponential parameter function is not constant, and the transition times of X are no longer the arrival times of the Poisson process. Nonetheless, many of the basic results above still apply.

Let  $X = \{X_t : t \in [0,\infty)\}$  be the Markov chain constructed in the previous theorem. Then

1. For  $t \in [0, \infty)$ , the transition matrix  $P_t$  is given by

$$P_t = \sum_{n=0}^{\infty} e^{-rt} \frac{(rt)^n}{n!} Q^n$$
(16.20.11)

2. For  $\alpha \in (0, \infty)$ , the  $\alpha$  potential matrix is given by

$$U_{\alpha} = \frac{1}{\alpha + r} \sum_{n=0}^{\infty} \left(\frac{r}{\alpha + r}\right)^n Q^n \tag{16.20.12}$$

3. The generator matrix is G = r(Q - I)

4.  $g: S \to (0, \infty)$  is invariant for  $\boldsymbol{X}$  if and only if g is invariant for  $\boldsymbol{Y}$ .

Proof

The proofs are just as before.

It's a remarkable fact that every continuous-time Markov chain with bounded exponential parameters can be constructed as in the last theorem, a process known as *uniformization*. The name comes from the fact that in the construction, the exponential parameters become constant, but at the expense of allowing the embedded discrete-time chain to jump from a state back to that state. To review the definition, suppose that  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  is a continuous-time Markov chain on S with transition semigroup  $\mathbf{P} = \{P_t : t \in [0, \infty)\}$ , exponential parameter function  $\lambda$  and jump transition matrix Q. Then  $\mathbf{P}$  is *uniform* if  $P_t(x, x) \to 1$  as  $t \downarrow 0$  uniformly in x, or equivalently if  $\lambda$  is bounded.

Suppose that  $\lambda : S \to (0, \infty)$  is bounded and that Q is a transition matrix on S with Q(x, x) = 0 for every  $x \in S$ . Let  $r \in (0, \infty)$  be an upper bound on  $\lambda$  and  $\mathbf{N} = \{N_t : t \in [0, \infty)\}$  a Poisson counting process with rate r. Define the transition matrix  $\hat{Q}$  on S by

$$egin{aligned} \hat{Q}(x,x) &= 1 - rac{\lambda(x)}{r} \quad x \in S \ \hat{Q}(x,y) &= rac{\lambda(x)}{r}Q(x,y) \quad (x,y) \in S^2, \, x 
eq y \end{aligned}$$

and let  $Y = \{Y_n : n \in \mathbb{N}\}$  be a discrete-time Markov chain with transition matrix  $\hat{Q}$ , independent of N. Define  $X_t = Y_{N_t}$  for  $t \in [0, \infty)$ . Then  $X = \{X_t : t \in [0, \infty)\}$  is a continuous-time Markov chain with exponential parameter function  $\lambda$  and jump transition matrix Q.

Proof

Note that  $\hat{Q}(x,y) \ge 0$  for every  $(x,y) \in S^2$  and  $\sum_{y \in S} \hat{Q}(x,y) = 1$  for every  $x \in S$ . Thus  $\hat{Q}$  is a transition matrix on S. Note also that  $\hat{Q}(x,x) < 1$  for every  $x \in S$ . By construction,  $\lambda(x) = r[1 - \hat{Q}(x,x)]$  for  $x \in S$  and

$$Q(x,y) = rac{Q(x,y)}{1-\hat{Q}(x,x)}, \quad (x,y) \in S^2, \ x 
eq y$$
 (16.20.13)

So the result now follows from the theorem above.

Note in particular that if the state space S is finite then of course  $\lambda$  is bounded so the previous theorem applies. The theorem is useful for simulating a continuous-time Markov chain, since the Poisson process and discrete-time chains are simple to simulate. In addition, we have nice representations for the transition matrices, potential matrices, and the generator matrix.

Suppose that  $X = \{X_t : t \in [0, \infty\}$  is a continuous-time Markov chain on S with bounded exponential parameter function  $\lambda : S \to (0, \infty)$  and jump transition matrix Q. Define r and  $\hat{Q}$  as in the last theorem. Then

1. For  $t \in [0,\infty)$ , the transition matrix  $P_t$  is given by

$$P_t = \sum_{n=0}^{\infty} e^{-rt} \frac{(rt)^n}{n!} \hat{Q}^n$$
(16.20.14)

2. For  $\alpha \in (0, \infty)$ , the  $\alpha$  potential matrix is given by

$$U_{\alpha} = \frac{1}{\alpha + r} \sum_{n=0}^{\infty} \left(\frac{r}{\alpha + r}\right)^n \hat{Q}^n$$
(16.20.15)

3. The generator matrix is  $G = r(\hat{Q} - I)$ 

4.  $g: S \to (0, \infty)$  is invariant for **X** if and only if g is invariant for  $\hat{Q}$ .

### Proof

These results follow from the theorem above.

## Examples

## The Two-State Chain

The following exercise applies the uniformization method to the two-state chain.

Consider the continuous-time Markov chain  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  on  $S = \{0, 1\}$  with exponential parameter function  $\lambda = (a, b)$ , where  $a, b \in (0, \infty)$ . Thus, states 0 and 1 are stable and the jump chain has transition matrix

$$Q = \begin{bmatrix} 0 & 1\\ 1 & 0 \end{bmatrix}$$
(16.20.16)

Let r = a + b , an upper bound on  $\lambda$ . Show that

1. 
$$\hat{Q} = \frac{1}{a+b} \begin{bmatrix} b & a \\ b & a \end{bmatrix}$$
  
2.  $G = \begin{bmatrix} -a & a \\ b & -b \end{bmatrix}$   
3.  $P_t = \hat{Q} - \frac{1}{a+b} e^{-(a+b)t} G$  for  $t \in [0, \infty)$   
4.  $U_{\alpha} = \frac{1}{\alpha} \hat{Q} - \frac{1}{(\alpha+a+b)(a+b)} G$  for  $\alpha \in (0, \infty)$ 

Proof

The form of  $\hat{Q}$  follows easily from the definition <u>above</u>. Note that the rows of  $\hat{Q}$  are the invariant PDF. It then follows that  $\hat{Q}^n = \hat{Q}$  for  $n \in \mathbb{N}_+$ . The results for the transition matrix  $P_t$  and the potential  $U_{\alpha}$  then follow easily from the theorem above.

Although we have obtained all of these results for the two-state chain before, the derivation based on uniformization is the easiest.

# 16.21: Continuous-Time Birth-Death Chains

## Basic Theory

### Introduction

A continuous-time *birth-death chain* is a simple class of Markov chains on a subset of  $\mathbb{Z}$  with the property that the only possible transitions are to increase the state by 1 (*birth*) or decrease the state by 1 (*death*). It's easiest to define the birth-death process in terms of the exponential transition rates, part of the basic structure of continuous-time Markov chains.

Suppose that *S* is an integer interval (that is, a set of consecutive integers), either finite or infinite. The *birth-death chain* with birth rate function  $\alpha : S \to [0, \infty)$  and death rate function  $\beta : S \to [0, \infty)$  is the Markov chain  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  on *S* with transition rate  $\alpha(x)$  from *x* to x + 1 and transition rate  $\beta(x)$  from *x* to x - 1, for  $x \in S$ .

If *S* has a minimum element *m*, then of course we must have  $\beta(m) = 0$ . If  $\alpha(m) = 0$  also, then the boundary point *m* is absorbing. Similarly, if *S* has a maximum element *n* then we must have  $\alpha(n) = 0$ . If  $\beta(n) = 0$  also then the boundary point *n* is absorbing. If  $x \in S$  is not a boundary point, then typically we have  $\alpha(x) + \beta(x) > 0$ , so that *x* is stable. If  $\beta(x) = 0$  for all  $x \in S$ , then *X* is a *pure birth process*, and similarly if  $\alpha(x) = 0$  for all  $x \in S$  then *X* is a *pure death process*. From the transition rates, it's easy to compute the parameters of the exponential holding times in a state and the transition matrix of the embedded, discrete-time jump chain.

Consider again the birth-death chain X on S with birth rate function  $\alpha$  and death rate function  $\beta$ . As usual, let  $\lambda$  denote the exponential parameter function and Q the transition matrix for the jump chain.

1.  $\lambda(x)=lpha(x)+eta(x)$  for  $x\in S$ 2. If  $x\in S$  is stable, so that lpha(x)+eta(x)>0, then

$$Q(x,x+1)=rac{lpha(x)}{lpha(x)+eta(x)}, \quad Q(x,x-1)=rac{eta(x)}{lpha(x)+eta(x)}$$
(16.21.1)

Note that jump chain  $Y = (Y_0, Y_1, ...)$  is a discrete-time birth death chain. The probability functions p, q, and r of Y are given as follows: If  $x \in S$  is stable then

$$egin{aligned} p(x) &= Q(x,x+1) = rac{lpha(x)}{lpha(x)+eta(x)} \ q(x) &= Q(x,x-1) = rac{eta(x)}{lpha(x)+eta(x)} \ r(x) &= Q(x,x) = 0 \end{aligned}$$

If x is absorbing then of course p(x) = q(x) = 0 and r(x) = 1. Except for the initial state, the jump chain Y is deterministic for a pure birth process, with Q(x, x) = 1 if x is absorbing and Q(x, x + 1) = 1 if x is stable. Similarly, except for the initial state, Y is deterministic for a pure death process, with Q(x, x) = 1 if x is absorbing and Q(x, x + 1) = 1 if x is stable. Similarly, except for the initial state, Y is deterministic for a pure death process, with Q(x, x) = 1 if x is absorbing and Q(x, x - 1) = 1 if x is stable. Note that the Poisson process with rate parameter  $r \in (0, \infty)$ , viewed as a continuous-time Markov chain, is a pure birth process on  $\mathbb{N}$  with birth function  $\alpha(x) = r$  for each  $x \in \mathbb{N}$ . More generally, a birth death process with  $\lambda(x) = \alpha(x) + \beta(x) = r$  for all  $x \in S$  is also subordinate to the Poisson process with rate r.

Note that  $\lambda$  is bounded if and only if  $\alpha$  and  $\beta$  are bounded (always the case if *S* is finite), and in this case the birth-death chain  $X = \{X_t : t \in [0, \infty)\}$  is uniform. If  $\lambda$  is unbounded, then X may not even be regular, as an example below shows. Recall that a sufficient condition for X to be regular when *S* is infinite is

$$\sum_{x \in S_+} \frac{1}{\lambda(x)} = \sum_{x \in S_+} \frac{1}{\alpha(x) + \beta(x)} = \infty$$
(16.21.2)

where  $S_+ = \{x \in S : \lambda(x) = \alpha(x) + \beta(x) > 0\}$  is the set of stable states. Except for the aforementioned example, we will restrict our study to regular birth-death chains.

### Infinitesimal Generator and Transition Matrices

Suppose again that  $X = \{X_t : t \in [0, \infty)\}$  is a continuous-time birth-death chain on an interval  $S \subseteq \mathbb{Z}$  with birth rate function  $\alpha$  and death rate function  $\beta$ . As usual, we will let  $P_t$  denote the transition matrix at time  $t \in [0, \infty)$  and G the infinitesimal generator. As always, the infinitesimal generator gives the same information as the exponential parameter function and the jump transition matrix, but in a more compact and useful form.

The generator matrix G is given by

$$G(x,x) = -[lpha(x) + eta(x)], \; G(x,x+1) = lpha(x), \; G(x,x-1) = eta(x), \quad x \in S \; (16.21.3)$$

Proof

This follows from the general theory, since  $G(x,x) = -\lambda(x)$  for  $x \in S$  and  $G(x,y) = \lambda(x)Q(x,y)$  for  $(x,y) \in S^2$  with  $x \neq y$ .

The Kolmogorov backward and forward equations are

 $\begin{array}{l} 1. \ \frac{d}{dt}P_t(x,y) = -[\alpha(x) + \beta(x)]P_t(x,y) + \alpha(x)P_t(x+1,y) + \beta(x)P_t(x-1,y) \ \text{for} \ (x,y) \in S^2. \\ 2. \ \frac{d}{dt}P_t(x,y) = -[\alpha(y) + \beta(y)]P_t(x,y) + \alpha(y-1)P_t(x,y-1) + \beta(y+1)P_t(x,y+1) \ \text{ for} \ (x,y) \in S^2 \\ \text{Proof} \end{array}$ 

These results follow from the generator matrix G above.

- 1. The backward equation is  $\frac{d}{dt}P_t = GP_t$ .
- 2. The forward equation is  $\frac{d}{dt}P_t = P_t G$ .

### Limiting Behavior and Stationary Distributions

For our discussion of limiting behavior, we will consider first the important special case of a continuous-time birth-death chain  $X = \{X_t : t \in [0, \infty)\}$  on  $S = \mathbb{N}$  and with  $\alpha(x) > 0$  for all  $x \in \mathbb{N}$  and  $\beta(x) > 0$  for all  $x \in \mathbb{N}_+$ . For the jump chain  $Y = \{Y_n : n \in \mathbb{N}\}$ , recall that

$$p(x)=Q(x,x+1)=rac{lpha(x)}{lpha(x)+eta(x)}, \; q(x)=Q(x,x-1)=rac{eta(x)}{lpha(x)+eta(x)}, \quad x\in\mathbb{N}$$

The jump chain Y is a discrete-time birth-death chain, and our notation here is consistent with the notation that we used in that section. Note that X and Y are irreducible. We first consider transience and recurrence.

The chains *X* and *Y* are recurrent if and only if

$$\sum_{x=0}^{\infty} \frac{\beta(1)\cdots\beta(x)}{\alpha(1)\cdots\alpha(x)} = \infty$$
(16.21.5)

Proof

Recall that X is recurrent if and only if Y is recurrent. In our study of discrete-time birth-death chains we saw that Y is recurrent if and only if

$$\sum_{x=0}^{\infty} \frac{q(1)\cdots q(x)}{p(1)\cdots p(x)} = \infty$$
(16.21.6)

But trivially,

$$\frac{q(1)\cdots q(x)}{p(1)\cdots p(x)} = \frac{\beta(1)\cdots\beta(x)}{\alpha(1)\cdots\alpha(x)}$$
(16.21.7)

Next we consider positive recurrence and invariant distributions. It's nice to look at this from different points of view.

```
The function g:\mathbb{N}	o (0,\infty) defined by
```

$$g(x)=rac{lpha(0)\cdotslpha(x-1)}{eta(1)\cdotseta(x)}, \quad x\in\mathbb{N}$$
 (16.21.8)

is invariant for X, and is the only invariant function, up to multiplication by constants. Hence X is positive recurrent if and only if  $B = \sum_{x=0}^{\infty} g(x) < \infty$ , in which case the (unique) invariant probability density function f is given by  $f(x) = \frac{1}{B}g(x)$  for  $x \in \mathbb{N}$ . Moreover,  $P_t(x, y) \to f(y)$  as  $t \to \infty$  for every  $x, y \in \mathbb{N}$ 

Proof using the jump chain

From our study of discrete-time birth-death chains, we know that the function  $h:\mathbb{N} o (0,\infty)$  defined by

$$h(x) = rac{p(0) \cdots p(x-1)}{q(1) \cdots q(x)}, \quad x \in \mathbb{N}$$
 (16.21.9)

is invariant for  $\boldsymbol{Y}$ , and is the only positive invariant function up to multiplication by positive constants. It then follows from our study of invariant functions for continuous-time chains that the function  $h/\lambda$  is invariant for  $\boldsymbol{X}$ , and again is the only positive invariant function up to multiplication by positive constants. But it's simple to see that

$$\frac{h(x)}{\lambda(x)} = \frac{h(x)}{\alpha(x) + \beta(x)} = \frac{\alpha(1) \cdots \alpha(x-1)}{\beta(1) \cdots \beta(x)} = \frac{1}{\alpha(0)}g(x)$$
(16.21.10)

where g is the function given in the theorem. The remaining parts of the theorem follow from the general theory.

Proof from the balance equation

A function  $g : \mathbb{N} \to (0, \infty)$  is invariant for X if and only if it satisfies the balance equation gG = 0. For our birth-death chain, this reduces to

$$lpha(0)g(0)=eta(1)g(1) \ [lpha(x)+eta(x)]g(x)=lpha(x-1)g(x-1)+eta(x+1)g(x+1), \quad x\in\mathbb{N}_+$$

Substituting the equation with x = 0 on the left into the equation with x = 1 on the left gives  $\alpha(1)g(1) = \beta(2)g(2)$ . Substituting this into the equation with x = 2 on the left gives  $\alpha(2)g(2) = \beta(3)g(3)$ . In general, the balance equations imply

$$lpha(x)g(x)=eta(x+1)g(x+1), \quad x\in\mathbb{N}$$

$$(16.21.11)$$

Solving these new balance equations recursively gives

$$g(x) = g(0) \frac{\alpha(0) \cdots \alpha(x-1)}{\beta(1) \cdots \beta(x)}$$

$$(16.21.12)$$

Letting g(0) = 1 gives the particular invariant function in the theorem. Again, the remaining parts follow from the general theory.

Here is a summary of the classification:

For the continuous-time birth-death chain X, let

$$A = \sum_{x=0}^{\infty} \frac{\beta(1)\cdots\beta(x)}{\alpha(1)\cdots\alpha(x)}, \ B = \sum_{x=0}^{\infty} \frac{\alpha(0)\cdots\alpha(x-1)}{\beta(1)\cdots\beta(x)}$$
(16.21.13)

- 1.  $\boldsymbol{X}$  is transient if  $A < \infty$ .
- 2. *X* is null recurrent if  $A = \infty$  and  $B = \infty$ .
- 3. *X* is positive recurrent if  $B < \infty$ .

Suppose now that  $n \in \mathbb{N}_+$  and that  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  is a continuous-time birth-death chain on the integer interval  $\mathbb{N}_n = \{0, 1, ..., n\}$ . We assume that  $\alpha(x) > 0$  for  $x \in \{0, 1, ..., n-1\}$  while  $\beta(x) > 0$  for  $x \in \{1, 2, ..., n\}$ . Of course, we must have  $\beta(0) = \alpha(n) = 0$ . With these assumptions,  $\mathbf{X}$  is irreducible, and since the state space is finite, positive recurrent. So all that remains is to find the invariant distribution. The result is essentially the same as when the state space is  $\mathbb{N}$ .

The invariant probability density function  $f_n$  is given by

$$f_n(x) = \frac{1}{B_n} \frac{\alpha(0) \cdots \alpha(x-1)}{\beta(1) \cdots \beta(x)} \text{ for } x \in \mathbb{N}_n \text{ where } B_n = \sum_{x=0}^n \frac{\alpha(0) \cdots \alpha(x-1)}{\beta(1) \cdots \beta(x)}$$
(16.21.14)

Proof

Define

$$g_n(x) = rac{lpha(0)\cdotslpha(x-1)}{eta(1)\cdotseta(x)}, \quad x \in \mathbb{N}_n$$
(16.21.15)

The proof thet  $g_n$  is invariant for X is the same as before. The constant  $B_n$  is the normalizing constant.

Note that  $B_n \to B$  as  $n \to \infty$ , and if  $B < \infty$ ,  $f_n(x) \to f(x)$  as  $n \to \infty$  for  $x \in \mathbb{N}$ . We will see this type of behavior again. Results for the birth-death chain on  $\mathbb{N}_n$  often converge to the corresponding results for the birth-death chain on  $\mathbb{N}$  as  $n \to \infty$ .

#### Absorption

Often when the state space  $S = \mathbb{N}$ , the state of a birth-death chain represents a *population* of individuals of some sort (and so the terms *birth* and *death* have their usual meanings). In this case state 0 is absorbing and means that the population is extinct. Specifically, suppose that  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  is a regular birth-death chain on  $\mathbb{N}$  with  $\alpha(0) = \beta(0) = 0$  and with  $\alpha(x), \beta(x) > 0$  for  $x \in \mathbb{N}_+$ . Thus, state 0 is absorbing and all positive states lead to each other and to 0. Let  $T = \min\{t \in [0, \infty) : X_t = 0\}$  denote the time until absorption, where as usual,  $\min \emptyset = \infty$ . Many of the results concerning extinction of the continuous-time birth-death chain follow easily from corresponding results for the discrete-time birth-death jump chain.

One of the following events will occur:

1. *Population extinction*:  $T < \infty$  or equivalently,  $X_s = 0$  for some  $s \in [0, \infty)$  and hence  $X_t = 0$  for all  $t \in [s, \infty)$ .

2. *Population explosion*:  $T = \infty$  or equivalently  $X_t \to \infty$  as  $t \to \infty$ .

Proof

Part (b) follows from the general theory, since 0 is absorbing, and all positive states lead to each other and to 0. Thus the positive states are transient and we know that with probability 1, the jump chain will visit a transient state only finitely often. Thus  $T = \infty$  is equivalent to  $X_t \to \infty$  as  $t \to \infty$ . Without the assumption that the chain is regular, population explosion could occur in finite time.

Naturally we would like to find the probability of these complementary events, and happily we have already done so in our study of discrete-time birth-death chains. The absorption probability function v is defined by

$$v(x)=\mathbb{P}(T<\infty)=\mathbb{P}(X_t=0 ext{ for some } t\in [0,\infty) \mid X_0=x), \quad x\in \mathbb{N}$$

As before, let

$$A = \sum_{i=0}^{\infty} \frac{\beta(1) \cdots \beta(i)}{\alpha(1) \cdots \alpha(i)}$$
(16.21.17)

1. If  $A = \infty$  then v(x) = 1 for all  $x \in \mathbb{N}$ . 2. If  $A < \infty$  then

$$v(x) = rac{1}{A} \sum_{i=x}^{\infty} rac{eta(1)\cdotseta(i)}{lpha(1)\cdotslpha(i)}, \quad x \in \mathbb{N}$$
 (16.21.18)

Proof

The continuous-time chain is absorbed into 0 if and only if the discrete-time jump chain is absorbed into 0. So the result follows from the corresponding result for discrete-time birth-death chains. Recall again that  $q(x)/p(x) = \beta(x)/\alpha(x)$  for  $x \in \mathbb{N}_+$ 

The mean time to extinction is considered next, so let  $m(x) = \mathbb{E}(T \mid X_0 = x)$  for  $x \in \mathbb{N}$ . Unlike the probability of extinction, computing the mean time to extinction cannot be easily reduced to the corresponding discrete-time computation. However, the

*method* of computation does extend.

The mean absorption function is given by

$$m(x) = \sum_{j=1}^{x} \sum_{k=j-1}^{\infty} rac{lpha(j)\cdots lpha(k)}{eta(j)\cdots eta(k+1)}, \quad x \in \mathbb{N}$$
 (16.21.19)

Probabilisitic Proof

The time required to go from state  $x \in \mathbb{N}_+$  to x - 1 has the same distribution as the time required to go from state 1 to 0, except with parameters  $\alpha(y)$ ,  $\beta(y)$  for  $y \in \{x, x + 1, \ldots\}$  instead of parameters  $\alpha(y)$ ,  $\beta(y)$  for  $y \in \{1, 2, \ldots\}$ . So by the additivity of expected value, we just need to compute m(1) as a function of the parameters. Starting in state 1, the chain will be absorbed in state 0 after a random number of returns to state 1 without absorption. Whenever the chain is in state 1, absorption occurs at the next transition with probability q(1) so it follows that the number of times that the chain is in state 1 before absorption has the geometric distribution on  $\mathbb{N}_+$  with success parameter q(1). The mean of this distribution is  $1/q(1) = [\alpha(1) + \beta(1)]/\beta(1)$ . On the other hand, starting in state 1, time until the chain is in state 1 again (without absorption) has the same distribution as the return time to state 0, starting in state 0 for the irreducible birth-death chain on  $\mathbb{N}$  with birth and death rates  $\alpha'$  and  $\beta'$  given by  $\alpha'(x) = \alpha(x+1)$  for  $x \in \mathbb{N}$  and  $\beta'(x) = \beta(x+1)$  for  $x \in \mathbb{N}_+$ . Thus, let

$$\mu = \frac{1}{\alpha(1) + \beta(1)} \sum_{k=0}^{\infty} \frac{\alpha(1) \cdots \alpha(k)}{\beta(2) \cdots \beta(k+1)}$$
(16.21.20)

Then  $\mu$  is the mean return time to state 0 for the chain X'. Specifically, note that if  $\mu = \infty$  then X' is either transient or null recurrent. If  $\mu < \infty$  then  $1/\mu$  is the invariant PDF at 0. So, it follows that

$$m(1) = \frac{1}{q(1)}\mu = \sum_{k=0}^{\infty} \frac{\alpha(1)\cdots\alpha(k)}{\beta(1)\cdots\beta(k+1)}$$
(16.21.21)

By our argument above, the mean time to go from state x to x - 1 is

$$\sum_{k=x-1}^{\infty} \frac{\alpha(x)\cdots\alpha(k)}{\beta(x)\cdots\beta(k+1)}$$
(16.21.22)

In particular, note that

$$m(1) = \sum_{k=0}^{\infty} \frac{\alpha(1)\cdots\alpha(k)}{\beta(1)\cdots\beta(k+1)}$$
(16.21.23)

If  $m(1)=\infty$  then  $m(x)=\infty$  for all  $x\in S.$  If  $m(1)<\infty$  then  $m(x)<\infty$  for all  $x\in S$ 

Next we will consider a birth-death chain on a finite integer interval with both endpoints absorbing. Our interest is in the probability of absorption in one endpoint rather than the other, and in the mean time to absorption. Thus suppose that  $n \in \mathbb{N}_+$  and that  $X = \{X_t : t \in [0, \infty)\}$  is a continuous-time birth-death chain on  $\mathbb{N}_n = \{0, 1, \ldots, n\}$  with  $\alpha(0) = \beta(0) = 0$ ,  $\alpha(n) = \beta(n) = 0$ , and  $\alpha(x) > 0$ ,  $\beta(x) > 0$  for  $x \in \{1, 2, \ldots, n-1\}$ . So the endpoints 0 and n are absorbing, and all other states lead to each other and to the endpoints. Let  $T = \inf\{t \in [0, \infty) : X_t \in \{0, n\}\}$ , the time until absorption, and for  $x \in S$  let  $v_n(x) = \mathbb{P}(X_T = 0 \mid X_0 = x)$  and  $m_n(x) = \mathbb{E}(T \mid X_0 = x)$ . The definitions make sense since T is finite with probability 1.

The absorption probability function for state 0 is given by

$$v_n(x) = \frac{1}{A_n} \sum_{i=x}^{n-1} \frac{\beta(1)\cdots\beta(i)}{\alpha(1)\cdots\alpha(i)} \text{ for } x \in \mathbb{N}_n \text{ where } A_n = \sum_{i=0}^{n-1} \frac{\beta(1)\cdots\beta(i)}{\alpha(1)\cdots\alpha(i)}$$
(16.21.24)

Proof

The jump chain  $\mathbf{Y} = \{Y_n : n \in \mathbb{N}\}\$  is a discrete-time birth-death chain on  $\mathbb{N}_n$  with 0 and *n* absorbing. Also,  $\mathbf{X}$  is absorbed into 0 or *n* if and only if  $\mathbf{Y}$  is absorbed into 0 or *n*, respectively. So the result follows from the corresponding result for  $\mathbf{Y}$ , since  $q(x)/p(x) = \beta(x)/\alpha(x)$  for  $x \in \{1, 2, ..., n-1\}$ .

Note that  $A_n \to A$  as  $n \to \infty$  where A is the constant above for the absorption probability at 0 with the infinite state space  $\mathbb{N}$ . If  $A < \infty$  then  $v_n(x) \to v(x)$  as  $n \to \infty$  for  $x \in \mathbb{N}$ .

## Time Reversal

Essentially, every irreducible continuous-time birth-death chain is reversible.

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  is a positive recurrent birth-death chain on an integer interval  $S \subseteq \mathbb{Z}$  with birth rate function  $\alpha : S \to [0, \infty)$  and death rate function  $\beta : S \to \infty$ . Assume that  $\alpha(x) > 0$ , except at the maximum value of S, if there is one, and similarly that  $\beta(x) > 0$ , except at the minimum value of X, if there is one. Then X is reversible.

## Proof

Note that X is irreducible. As usual, let G denote the generator matrix. It's easy to see that under the assumptions, G(x, y) = 0 implies G(y, x) = 0 for  $(x, y) \in S^2$ , and that the Kolmogorov cycle condition is satisfied: For every  $n \in \mathbb{N}_+$  and every sequence  $(x_1, x_2, \dots, x_n) \in S^n$ ,

$$G(x_1, x_2) \cdots G(x_{n-1}, x_n) G(x_n, x_1) = G(x_1, x_n), G(x_n, x_{n-1} \cdots G(x_2, x_1)$$
(16.21.25)

In the important special case of a birth-death chain on  $\mathbb{N}$ , we can verify the balance equations directly.

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  is a continuous-time birth-death chain on  $S = \mathbb{N}$  and with birth rate  $\alpha(x) > 0$  for all  $x \in \mathbb{N}$  and death rate  $\beta(x) > 0$  for all  $x \in \mathbb{N}_+$ . Then X is reversible.

Proof

We just need to show that the balance equation for a reversible chain holds, and this was actually done in the result above. As before, let  $g : \mathbb{N} \to (0, \infty)$  be the function given by

$$g(x)=rac{lpha(0)\cdotslpha(x-1)}{eta(1)\cdotseta(x)}, \quad x\in\mathbb{N}$$
 (16.21.26)

The only nontrivial case of the balance equation g(x)G(x,y) = g(y)G(y,x) for  $(x,y) \in S^2$  is

$$g(x)G(x,x+1) = g(x+1)G(x+1,x)) = rac{lpha(0)\cdotslpha(x)}{eta(1)\cdotseta(x)}, \quad x \in \mathbb{N}$$
 (16.21.27)

It follows from the general theory that g is invariant for X and that X is reversible with respect to g. Since we actually know from our work above that g is the only positive invariant function, up to multiplication by positive constants, we can simply say that X is reversible.

In the positive recurrent case, it follows that the birth-death chain is stochastically the same, forward or backward in time, if the chain has the invariant distribution.

### **Examples and Special Cases**

### Regular and Irregular Chains

Our first exercise gives two pure birth chains, each with an unbounded exponential parameter function. One is regular and one is irregular.

Consider the pure birth process  $X = \{X_t : t \in [0, \infty)\}$  on  $\mathbb{N}_+$  with birth rate function  $\alpha$ .

1. If  $\alpha(x) = x^2$  for  $x \in \mathbb{N}_+$ , then X is not regular. 2. If  $\alpha(x) = x$  for  $x \in \mathbb{N}_+$ , then X is regular.

Proof

The jump chain  $m{Y}$  is deterministic, except for the initial state. Given  $Y_0=x\in\mathbb{N}_+$  , we have  $Y_n=n+x$  . Hence

1. 
$$\sum_{n=0}^{\infty} \frac{1}{\lambda(Y_n)} = \sum_{n=0}^{\infty} \frac{1}{(n+x)^2} < \infty$$
  
2.  $\sum_{n=0}^{\infty} \frac{1}{\lambda(Y_n)} = \sum_{n=0}^{\infty} \frac{1}{n+x} = \infty$ 

So the results follow from the general theory.

### Constant Birth and Death Rates

Our next examples consider birth-death chains with constant birth and death rates, except perhaps at the endpoints. Note that such chains will be regular since the exponential parameter function  $\lambda$  is bounded.

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  is the birth-death chain on  $\mathbb{N}$ , with constant birth rate  $\alpha \in (0, \infty)$  on  $\mathbb{N}$  and constant death rate  $\beta \in (0, \infty)$  on  $\mathbb{N}_+$ .

- 1. *X* is transient if  $\beta < \alpha$ .
- 2. *X* is null recurrent if  $\beta = \alpha$ .
- 3. *X* is positive recurrent if  $\beta > \alpha$ . The invariant distribution is the geometric distribution on  $\mathbb{N}$  with parameter  $\alpha/\beta$

$$f(x) = \left(1 - rac{lpha}{eta}
ight) \left(rac{lpha}{eta}
ight)^x, \quad x \in \mathbb{N}$$
 (16.21.28)

Proof

Note that X is irreducible since the birth rate is positive on  $\mathbb{N}$  and the death rate is positive on  $\mathbb{N}_+$ . The series in the results above are geometric series:

$$\frac{\beta(1)\cdots\beta(x)}{\alpha(1)\cdots\alpha(x)} = \left(\frac{\beta}{\alpha}\right)^x, \ \frac{\alpha(0)\cdots\alpha(x-1)}{\beta(1)\cdots\beta(x)} = \left(\frac{\alpha}{\beta}\right)^x, \quad x \in \mathbb{N}$$
(16.21.29)

Next we consider the chain with 0 absorbing. As in the general discussion above, let v denote the function that gives the probability of absorption and m the function that gives the mean time to absorption.

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  is the birth-death chain in  $\mathbb{N}$  with constant birth rate  $\alpha \in (0, \infty)$  on  $\mathbb{N}_+$ , constant death reate  $\beta \in (0, \infty)$  on  $\mathbb{N}_+$ , and with 0 absorbing. Then

1. If  $\beta \ge \alpha$  then v(x) = 1 for  $x \in \mathbb{N}$ . If  $\beta < \alpha$  then  $v(x) = (\beta/\alpha)^x$  for  $x \in \mathbb{N}$ . 2. If  $\alpha \ge \beta$  then  $m(x) = \infty$ . If  $\alpha < \beta$  then  $m(x) = x/(\beta - \alpha)$  for  $x \in \mathbb{N}$ .

Next let's look at chains on a finite state space. Let  $n \in \mathbb{N}_+$  and define  $\mathbb{N}_n = \{0, 1, \dots, n\}$ .

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  is a continuous-time birth-death chain on  $\mathbb{N}_n$  with constant birth rate  $\alpha \in (0, \infty)$  on  $\{0, 1, \ldots, n-1\}$  and constant death rate  $\beta \in (0, \infty)$  on  $\{1, 2, \ldots n\}$ . The invariant probability density function  $f_n$  is given as follows:

1. If  $\alpha \neq \beta$  then

$$f_n(x) = rac{(lpha/eta)^x(1-lpha/eta)}{1-(lpha/eta)^{n+1}}, \quad x \in \mathbb{N}_n$$
 $(16.21.30)$ 

2. If lpha=eta then  $f_n(x)=1/(n+1)$  for  $x\in\mathbb{N}_n$ 

Note that when  $\alpha = \beta$ , the invariant distribution is uniform on  $\mathbb{N}_n$ . Our final exercise considers the absorption probability at 0 when both endpoints are absorbing. Let  $v_n$  denote the function that gives the probability of absorption into 0, rather than n.

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  is the birth-death chain on  $\mathbb{N}_n$  with constant birth rate  $\alpha$  and constant death rate  $\beta$  on  $\{1, 2, \ldots, n-1\}$ , and with 0 and *n* absorbing.

1. If  $\alpha \neq \beta$  then

$$v_n(x) = rac{(eta/lpha)^x - (eta/lpha)^n}{1 - (eta/lpha)^n}, \quad x \in \mathbb{N}_n$$

$$(16.21.31)$$

2. If 
$$lpha=eta$$
 then  $v_n(x)=(n-x)/n\,$  for  $x\in\mathbb{N}_n$  .

## Linear Birth and Death Rates

For our next discussion, consider individuals that act identically and independently. Each individual splits into two at exponential rate  $a \in (0, \infty)$  and dies at exponential rate  $b \in (0, \infty)$ .

Let  $X_t$  denote the population at time  $t \in [0, \infty)$ . Then  $X = \{X_t : t \in [0, \infty)\}$  is a regular, continuous-time birth-death chain with birth and death rate functions given by  $\alpha(x) = ax$  and  $\beta(x) = bx$  for  $x \in \mathbb{N}$ .

Proof

The fact that X is a continuous-time Markov chain follows from the assumptions. Moreover, since the individuals act independently, the overall birth and death rates when the population is  $x \in \mathbb{N}$  is simple x times the individual birth and death rates. The chain is regular since

$$\sum_{x=1}^{\infty} \frac{1}{(a+b)x} = \infty$$
 (16.21.32)

Note that 0 is absorbing since the population is extinct, so as usual, our interest is in the probability of absorption and the mean time to absorption as functions of the initial state. The probability of absorption is the same as for the chain with constant birth and death rates discussed above.

The absorption probability function v is given as follows:

1. 
$$v(x) = 1$$
 for all  $x \in \mathbb{N}$  if  $b \ge a$ .  
2.  $v(x) = (b/a)^x$  for  $x \in \mathbb{N}$  if  $b < a$ .

Proof

These results follow from the general results above since  $\beta(x)/\alpha(x) = b/a$  for  $x \in \mathbb{N}_+$ . Hence for  $x \in \mathbb{N}$ ,

$$\sum_{i=x}^{\infty} (b/a)^i = egin{cases} \infty & b \ge a \ rac{(b/a)^x}{1-b/a} & b < a \end{cases}$$
 $(16.21.33)$ 

The mean time to absorption is more interesting.

The mean time to absorption function m is given as follows:

1. If  $a \geq b$  then  $m(x) = \infty$  for  $x \in \mathbb{N}_+$  . 2. If a < b then

$$m(x) = \sum_{j=1}^{x} rac{b^{j-1}}{a^j} \int_0^{a/b} rac{u^{j-1}}{1-u} du, \quad x \in \mathbb{N}$$
 (16.21.34)

Proof

1. From the general results above, note that

$$m(1) = \sum_{k=0}^{\infty} \frac{1}{(k+1)b} \left(\frac{a}{b}\right)^k$$
(16.21.35)

The sum is infinite if  $a \ge b$ .

2. If  $\alpha < \beta$  then again from the general formula above,

$$m(x) = \sum_{j=1}^{x} \sum_{k=j-1}^{\infty} \frac{1}{(k+1)b} \left(\frac{a}{b}\right)^{k-j+1} = \sum_{j=1}^{x} \frac{1}{b} \left(\frac{b}{a}\right)^{j} \sum_{k=j-1}^{\infty} \frac{1}{k+1} \left(\frac{a}{b}\right)^{k+1}$$
(16.21.36)

The inner series converges absolutely. Moreover, for  $k \in \mathbb{N}$  ,

$$\frac{1}{k+1} \left(\frac{a}{b}\right)^{k+1} = \int_0^{a/b} u^k du$$
 (16.21.37)

Substituting and interchanging the sum and integral gives

$$m(x) = \sum_{j=1}^{x} \frac{b^{j-1}}{a^j} \int_0^{a/b} \left( \sum_{k=j-1}^{\infty} u^k \right) du = \sum_{j=1}^{x} \frac{b^{j-1}}{a^j} \int_0^{a/b} \frac{u^{j-1}}{1-u} du$$
(16.21.38)

For small values of  $x \in \mathbb{N}$ , the integrals in the case a < b can be done by elementary methods. For example,

$$\begin{split} m(1) &= -\frac{1}{a} \ln \left( 1 - \frac{a}{b} \right) \\ m(2) &= m(1) - \frac{1}{a} - \frac{b}{a^2} \ln \left( 1 - \frac{a}{b} \right) \\ m(3) &= m(2) - \frac{1}{2a} - \frac{b}{a^2} - \frac{b^2}{a^3} \ln \left( 1 - \frac{a}{b} \right) \end{split}$$

However, a general formula requires the introduction of a special function that is not much more helpful than the integrals themselves. The Markov chain X is actually an example of a branching chain. We will revisit this chain in that section.

#### Linear Birth and Death with Immigration

We continue our previous discussion but generalizing a bit. Suppose again that we have individuals that act identically and independently. An individual splits into two at exponential rate  $a \in [0, \infty)$  and dies at exponential rate  $b \in [0, \infty)$ . Additionally, new individuals enter the population at exponential rate  $c \in [0, \infty)$ . This is the *immigration effect*, and when c = 0 we have the birth-death chain in the previous discussion.

Let  $X_t$  denote the population at time  $t \in [0, \infty)$ . Then  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  is a regular, continuous-time birth-death chain with birth and death rate functions given by  $\alpha(x) = ax + c$  and  $\beta(x) = bx$  for  $x \in \mathbb{N}$ .

Proof

The fact that X is a continuous-time Markov chain follows from the assumptions. Moreover, since the individuals act independently, the overall birth rate when the population is  $x \in \mathbb{N}$  is ax + c while the death rate is bx. The chain is regular since

$$\sum_{x=1}^{\infty} \frac{1}{((a+b)x+c)} = \infty$$
(16.21.39)

The infinitesimal matrix G is given as follows, for  $x \in \mathbb{N}$ :

 $\begin{array}{l} 1.\;G(x,x)=-[(a+b)x+c]\\ 2.\;G(x,x+1)=ax+c\\ 3.\;G(x,x-1)=bx \end{array}$ 

The backward and forward equations are given as follows, for  $(x,y) \in \mathbb{N}^2$  and  $t \in (0,\infty)$ 

$$\begin{array}{l} 1. \ \frac{d}{dt} P_t(x,y) = -[(a+b)x+c] P_t(x,y) + (ax+c) P_t(x+1,y) + bx P_t(x-1,y) \\ 2. \ \frac{d}{dt} P_t(x,y) = -[(a+b)y+c] P_t(x,y) + [a(y-1)+c] P_t(x,y-1) + b(y+1) P_t(x,y+1 \ ) \end{array}$$

We can use the forward equation to find the expected population size. Let  $M_t(x) = \mathbb{E}(X_t, | X_0 = x)$  for  $t \in [0, \infty)$  and  $x \in \mathbb{N}$ .

For  $t \in [0,\infty)$  and  $x \in \mathbb{N}$ , the mean population size  $M_t(x)$  is given as follows: 1. If a = b then  $M_t(x) = ct + x$ . 2. If  $a \neq b$  then  $M_t(x) = \frac{c}{a-b} \left[ e^{(a-b)t} - 1 \right] + x e^{(a-b)t}$ 

Proof

First note that  $M_t(x) = \sum_{y=0}^{\infty} y P_t(x, y)$  for  $x \in \mathbb{N}$ . Multiplying the forward equation above by y and summing over  $y \in \mathbb{N}$  gives

(16.21.40)

$$egin{aligned} &\sum_{y=0}^\infty y rac{d}{dt} P_t(x,y) = a \sum_{y=2}^\infty y(y-1) P_t(x,y-1) + c \sum_{y=1}^\infty y P_t(x,y-1) \ &- (a+b) \sum_{y=0}^\infty y^2 P_t(x,y) - c \sum_{y=0}^\infty y P_t(x,y) + b \sum_{y=0}^\infty y(y+1) P_t(x,y+1) \end{aligned}$$

Re-indexing the sums and using some algebra gives the first-order differential equation

$$rac{d}{dt}M_t(x) = c + (a-b)M_t(x), \quad x \in \mathbb{N}, \ t \in (0,\infty)$$
 (16.21.41)

with initial condition  $M_0(x) = x$ . Solving the differential equation gives the result.

Note that b > a, so that the individual death rate exceeds the birth rate, then  $M_t(x) \to c/(b-a)$  as  $t \to \infty$  for  $x \in \mathbb{N}$ . If  $a \ge b$  so that the birth rate equals or exceeds the death rate, then  $M_t(x) \to \infty$  as  $t \to \infty$  for  $x \in \mathbb{N}_+$ .

Next we will consider the special case with no births, but only death and immigration. In this case, the invariant distribution is easy to compute, and is one of our favorites.

Suppose that a = 0 and that b, c > 0. Then **X** is positive recurrent. The invariant distribution is Poisson with parameter c/b:

$$f(x) = e^{-c/b} \frac{(c/b)^x}{x!}, \quad x \in \mathbb{N}$$
 (16.21.42)

Proof

In terms of the general theory above, note that the invariant function g, unique up to multiplication by positive constants, is given by

$$g(x)=rac{lpha(0)\cdotslpha(x)}{eta(1)\cdotseta(x)}=rac{c^x}{b^xx!}=rac{(c/b)^x}{x!},\quad x\in\mathbb{N}$$
 (16.21.43)

Hence  $B = \sum_{x=0}^{\infty} g(x) = e^{c/b} < \infty$  and therefore the chain is positive recurrent with invariant PDF

$$f(x) = rac{1}{B}g(x) = e^{-c/b}rac{(c/b)^x}{x!}, \quad x \in \mathbb{N}$$
 (16.21.44)

This is the PDF of the Poisson distribution with parameter c/b.

## The Logistics Chain

Consider a population that fluctuates between a minimum value  $m \in \mathbb{N}_+$  and a maximum value  $n \in \mathbb{N}_+$ , where of course, m < n. Given the population size, the individuals act independently and identically. Specifically, if the population is  $x \in \{m, m+1, \ldots, n\}$  then an individual splits in two at exponential rate a(n-x) and dies at exponential rate b(x-m), where  $a, b \in (0, \infty)$ . Thus, an individual's birth rate decreases linearly with the population size from a(n-m) to 0 while the death rate increases linearly with the population size from 0 to b(n-m). These assumptions lead to the following definition.

The continuous-time birth-death chain  $X = \{X_t : t \in [0, \infty)\}$  on  $S = \{m, m+1, \ldots, n\}$  with birth rate function  $\alpha$  and death rate function  $\beta$  given by

$$lpha(x)=ax(n-x),\ eta(x)=bx(x-m),\quad x\in S$$

$$(16.21.45)$$

is the *logistic chain* on *S* with parameters *a* and *b*.

Justification

Since the individuals act independently and identically, the overall birth rate and death rates when the population is  $x \in S$  is simply x times the birth and death rate for an individual.

Note that the logistics chain is a stochastic counterpart of the logistics differential equation, which typically has the form

$$\frac{dx}{dt} = c(x-m)(n-x)$$
(16.21.46)

where m, n,  $c \in (0, \infty)$  and m < n. Starting in  $x(0) \in (m, n)$ , the solution remains in (m, n) for all  $t \in [0, \infty)$ . Of course, the logistics differential equation models a system that is continuous in time and space, whereas the logistics Markov chain models a system that is continuous in time and discrete is space.

#### For the logistics chain

1. The exponential parameter function  $\lambda$  is given by

$$\lambda(x) = ax(n-x) + bx(x-m), \quad x \in S$$
 (16.21.47)

2. The transition matrix Q of the jump chain is given by

$$Q(x,x-1)=rac{b(x-m)}{a(n-x)+b(x-m)}, \ Q(x,x+1)=rac{a(n-x)}{a(n-x)+b(x-m)}, \quad x\in S \qquad (16.21.48)$$

In particular, *m* and *n* are reflecting boundary points, and so the chain is irreducible.

The generator matrix *G* for the logistics chain is given as follows, for  $x \in S$ :

1. 
$$G(x, x) = -x[a(n-x)+b(x-m)]$$
  
2.  $G(x, x-1) = bx(x-m)$   
3.  $G(x, x+1) = ax(n-x)$ 

Since S is finite,  $\boldsymbol{X}$  is positive recurrent. The invariant distribution is given next.

Define 
$$g: S o (0,\infty)$$
 by

$$g(x)=rac{1}{x}inom{n-m}{x-m}inom{a}{b}^{x-m},\quad x\in S$$
(16.21.49)

Then g is invariant for X.

Proof

Since we know that X is reversible, we just need to show that g(x)G(x, y) = g(y)G(y, x) for  $(x, y) \in S^2$ . For the logistics chain, the only non-trivial equation is g(x)G(x, x+1) = g(x+1)G(x+1, x) for  $x \in S$ . Simple substitution and algebra show that both sides reduce to

$$\frac{(n-m)!}{(x-m)!(n-x-1)!} \frac{a^{x-m+1}}{b^{x-m}}$$
(16.21.50)

Of course it now follows that the invariant probability density function f for X is given by f(x) = g(x)/c for  $x \in S$  where c is the normalizing constant

$$c = \sum_{x=m}^{n} \frac{1}{x} \binom{n-m}{x-m} \left(\frac{a}{b}\right)^{x-m}$$
(16.21.51)

The limiting distribution of X has probability density function f.

### Other Special Birth-Death Chains

There are a number of special birth-death chains that are studied in other sections, because the models are important and lead to special insights and analytic tools. These include

- Queuing chains
- The pure death branching chain
- The Yule process, a pure birth branching chain
- The general birth-death branching chain

This page titled 16.21: Continuous-Time Birth-Death Chains is shared under a CC BY 2.0 license and was authored, remixed, and/or curated by Kyle Siegrist (Random Services) via source content that was edited to the style and standards of the LibreTexts platform.

# 16.22: Continuous-Time Queuing Chains

## Basic Theory

## Introduction

In a *queuing model*, *customers* arrive at a station for *service*. As always, the terms are generic; here are some typical examples:

- The customers are persons and the service station is a store.
- The customers are file requests and the service station is a web server.

Figure 16.22.1: Ten customers and a server

Queuing models can be quite complex, depending on such factors as the probability distribution that governs the arrival of customers, the probability distribution that governs the service of customers, the number of servers, and the behavior of the customers when all servers are busy. Indeed, queuing theory has its own lexicon to indicate some of these factors. In this section, we will discuss a few of the basic, continuous-time queuing chains. In a general sense, the main interest in any queuing model is the number of customers in the system as a function of time, and in particular, whether the servers can adequately handle the flow of customers. This section parallels the section on discrete-time queuing chains.

Our main assumptions are as follows:

- 1. There are  $k \in \mathbb{N}_+ \cup \{\infty\}$  servers.
- 2. The customers arrive according to a Poisson process with rate  $\mu \in (0, \infty)$ .
- 3. If all of the servers are busy, a new customer goes to the end of a single line of customers waiting service.
- 4. The time required to service a customer has an exponential distribution with parameter  $\nu \in (0, \infty)$ .
- 5. The service times are independent from customer to customer, and are independent of the arrival process.

Assumption (b) means that the times between arrivals of customers are independent and exponentially distributed, with parameter  $\mu$ . Assumption (c) means that we have a *first-in, first-out* model, often abbreviated *FIFO*. Note that there are three parameters in the model: the number of servers k, the exponential parameter  $\mu$  that governs the arrivals, and the exponential parameter  $\nu$  that governs the service times. The special cases k = 1 (a single server) and  $k = \infty$  (infinitely many servers) deserve special attention. As you might guess, the assumptions lead to a continuous-time Markov chain.

Let  $X_t$  denote the number of customers in the system (waiting in line or being served) at time  $t \in [0, \infty)$ . Then  $X = \{X_t : t \in [0, \infty)\}$  is a continuous-time Markov chain on  $\mathbb{N}$ , known as the *M*/*M*/*k* queuing chain.

In terms of the basic structure of the chain, the important quantities are the exponential parameters for the states and the transition matrix for the embedded jump chain.

For the M/M/k chain  $\boldsymbol{X}$ ,

- 1. The exponential parameter function  $\lambda$  is given by  $\lambda(x) = \mu + \nu x$  if  $x \in \mathbb{N}$  and x < k and  $\lambda(x) = \mu + \nu k$  if  $x \in \mathbb{N}$  and  $x \ge k$ .
- 2. The transition matrix Q for the jump chain is given by

$$egin{aligned} Q(x,x-1) &= rac{
u x}{\mu+
u x}, \ Q(x,x+1) = rac{\mu}{\mu+
u x}, \quad x \in \mathbb{N}, \ x < k \ Q(x,x-1) &= rac{
u k}{\mu+
u k}, \ Q(x,x+1) = rac{\mu}{\mu+
u k}, \quad x \in \mathbb{N}, x \geq k \end{aligned}$$

So the M/M/k chain is a birth-death chain with 0 as a reflecting boundary point. That is, in state  $x \in \mathbb{N}_+$ , the next state is either x - 1 or x + 1, while in state 0, the next state is 1. When k = 1, the single-server queue, the exponential parameter in state  $x \in \mathbb{N}_+$  is  $\mu + \nu$  and the transition probabilities for the jump chain are

$$Q(x, x-1) = \frac{\nu}{\mu + \nu}, \ Q(x, x+1) = \frac{\mu}{\mu + \nu}$$
(16.22.1)

When  $k = \infty$ , the infinite server queue, the cases above for  $x \ge k$  are vacuous, so the exponential parameter in state  $x \in \mathbb{N}$  is  $\mu + x\nu$  and the transition probabilities are

$$Q(x, x-1) = \frac{\nu x}{\mu + \nu x}, \ Q(x, x+1) = \frac{\mu}{\mu + \nu x}$$
(16.22.2)

#### Infinitesimal Generator

The infinitesimal generator of the chain gives the same information as the exponential parameter function and the jump transition matrix, but in a more compact form.

For the M/M/k queuing chain X, the infinitesimal generator G is given by

$$egin{array}{rll} G(x,x) &= -(\mu + 
u x), \; G(x,x-1) = 
u x, \; G(x,x+1) = \mu; & x \in \mathbb{N}, \; x < k \ G(x,x) &= -(\mu + 
u k), \; G(x,x-1) = 
u k, \; G(x,x+1) = \mu; & x \in \mathbb{N}, \; x \geq k \end{array}$$

So for k = 1, the single server queue, the generator G is given by  $G(0,0) = -\mu$ ,  $G(0,1) = \mu$ , while for  $x \in \mathbb{N}_+$ ,  $G(x,x) = -(\mu + \nu)$ ,  $G(x,x-1) = \nu$ ,  $G(x,x+1) = \mu$ . For  $k = \infty$ , the infinite server case, the generator G is given by  $G(x,x) = -(\mu + \nu x)$ ,  $G(x,x-1) = \nu x$ , and  $G(x,x+1) = \mu$  for all  $x \in \mathbb{N}$ .

### **Classification and Limiting Behavior**

Again, let  $X = \{X_t : t \in [0, \infty)\}$  denote the M/M/k queuing chain with arrival rate  $\mu$ , service rate  $\nu$  and with  $k \in \mathbb{N}_+ \cup \{\infty\}$  servers. As noted in the introduction, of fundamental importance is the question of whether the servers can handle the flow of customers, so that the queue eventually empties, or whether the length of the queue grows without bound. To understand the limiting behavior, we need to classify the chain as transient, null recurrent, or positive recurrent, and find the invariant functions. This will be easy to do using our results for more general continuous-time birth-death chains. Note first that X is irreducible. It's best to consider the single server and infinite server cases individually.

The single server queuing chain  $\boldsymbol{X}$  is

1. Transient if  $\nu < \mu$ .

2. Null recurrent if  $\nu = \mu$ .

3. Positive recurrent if  $\nu > \mu$ . The invariant distribution is the geometric distribution on  $\mathbb{N}$  with parameter  $\mu/\nu$ . The invariant probability density function *f* is given by

$$f(x) = \left(1 - \frac{\mu}{\nu}\right) \left(\frac{\mu}{\nu}\right)^x, \quad x \in \mathbb{N}$$
(16.22.3)

Proof

This follows directly from results for the continuous-time birth-death chain, with constant birth rate  $\mu$  on  $\mathbb{N}$  and constant death rate  $\nu$  on  $\mathbb{N}_+$ .

The result makes intuitive sense. If the service rate is less than the arrival rate, the chain is transient and the length of the queue grows to infinity. If the service rate is greater than the arrival rate, the chain is positive recurrent. At the boundary between these two cases, when the arrival and service rates are the same, the chain is null recurrent.

The infinite server queuing chain X is positive recurrent. The invariant distribution is the Poisson distribution with parameter  $\mu/\nu$ . The invariant probability density function f is given by

$$f(x) = e^{-\mu/
u} rac{(\mu/
u)^x}{x!}, \quad x \in \mathbb{N}$$
 (16.22.4)

Proof

This also follows from results for the continuous-time birth-death chain. In the notation of that section, the birth rate is constant,  $\mu(x) = \mu$  for  $x \in \mathbb{N}$  and the death rate is proportional to the number of customers in the system:  $\nu(x) = \nu x$  for  $x \in \mathbb{N}_+$ . Hence the invariant function (unique up to multiplication by constants) is

$$x \mapsto \frac{\mu(0) \cdots \mu(x-1)}{\nu(1) \cdots \nu(x)} = \frac{\mu^x}{\nu^x x!}$$
(16.22.5)

Normalized, this is the Poisson distribution with parameter  $\mu/\nu$ .

This result also makes intuitive sense.

# 16.23: Continuous-Time Branching Chains

## **Basic Theory**

#### Introduction

Generically, suppose that we have a system of *particles* that can generate or split into other particles of the same type. Here are some typical examples:

- The particles are biological organisms that reproduce.
- The particles are neutrons in a chain reaction.
- The particles are electrons in an electron multiplier.

We assume that the lifetime of each particle is exponentially distributed with parameter  $\alpha \in (0, \infty)$ , and at the end of its life, is replaced by a random number of new particles that we will refer to as *children* of the original particle. The number of children N of a particle has probability density function f on  $\mathbb{N}$ . The particles act independently, so in addition to being identically distributed, the lifetimes and the number of children are independent from particle to particle. Finally, we assume that f(1) = 0, so that a particle cannot simply die and be replaced by a single new particle. Let  $\mu$  and  $\sigma^2$  denote the mean and variance of the number of offspring of a single particle. So

$$\mu = \mathbb{E}(N) = \sum_{n=0}^{\infty} nf(n), \quad \sigma^2 = \operatorname{var}(N) = \sum_{n=0}^{\infty} (n-\mu)^2 f(n)$$
(16.23.1)

We assume that  $\mu$  is finite and so  $\sigma^2$  makes sense. In our study of discrete-time Markov chains, we studied branching chains in terms of *generational time*. Here we want to study the model in real time.

Let  $X_t$  denote the number of particles at time  $t \in [0, \infty)$ . Then  $X = \{X_t : t \in [0, \infty)\}$  is a continuous-time Markov chain on  $\mathbb{N}$ , known as a *branching chain*. The exponential parameter function  $\lambda$  and jump transition matrix Q are given by

 $egin{array}{lll} 1.\ \lambda(x)=lpha x ext{ for } x\in \mathbb{N} \ 2.\ Q(x,x+k-1)=f(k) ext{ for } x\in \mathbb{N}_+ ext{ and } k\in \mathbb{N}. \end{array}$ 

Proof

That X is a continuous-time Markov chain follows from the assumptions and the basic structure of continuous-time Markov chains. In turns out that the assumption that  $\mu < \infty$  implies that X is regular, so that  $\tau_n \to \infty$  as  $n \to \infty$ , where  $\tau_n$  is the time of the *n*th jump for  $n \in \mathbb{N}_+$ .

- 1. Starting with x particles, the time of the first state change is the minimum of x independent variables, each exponentially distributed with parameter  $\alpha$ . As we know, this minimum is also exponentially distributed with parameter  $\alpha x$ .
- 2. Starting in state  $x \in \mathbb{N}_+$ , the next state will be x + k 1 for  $k \in \mathbb{N}$ , if the particle dies and leaves k children in her place. This happens with probability f(k).

Of course 0 is an absorbing state, since this state means extinction with no particles. (Note that  $\lambda(0) = 0$  and so by default, Q(0,0) = 1.) So with a branching chain, there are essentially two types of behavior: population extinction or population explosion.

For the branching chain  $X = \{X_t : t \in [0, \infty)\}$  one of the following events occurs with probability 1:

1. Extinction:  $X_t = 0$  for some  $t \in [0, \infty)$  and hence  $X_s = 0$  for all  $s \ge t$ .

2. Explosion:  $X_t \to \infty$  as  $t \to \infty$ .

Proof

If f(0) > 0 then all states lead to the absorbing state 0 and hence the set of positive staties  $\mathbb{N}_+$  is transient. With probability 1, the jump chain Y visits a transient state only finitely many times, so with probability 1 either  $Y_n = 0$  for some  $n \in \mathbb{N}$  or  $Y_n \to \infty$  as  $n \to \infty$ . If f(0) = 0 then  $Y_n$  is strictly increasing in n, since f(1) = 0 by assumption. Hence with probability 1,  $Y_n \to \infty$  as  $n \to \infty$ .

Without the assumption that  $\mu < \infty$ , explosion can actually occur in finite time. On the other hand, the assumption that f(1) = 0 is for convenience. Without this assumption, X would still be a continuous-time Markov chain, but as discussed in the Introduction, the exponential parameter function would be  $\lambda(x) = \alpha f(1)x$  for  $x \in \mathbb{N}$  and the jump transition matrix would be

$$Q(x,x+k-1)=rac{f(k)}{1-f(1)}, \quad x\in\mathbb{N}_+,\; k\in\{0,2,3,\ldots\}$$
 (16.23.2)

Because all particles act identically and independently, the branching chain starting with  $x \in \mathbb{N}_+$  particles is essentially x independent copies of the branching chain starting with 1 particle. In many ways, this is the fundamental insight into branching chains, and in particular, means that we can often condition on X(0) = 1.

#### Generator and Transition Matrices

As usual, we will let  $P = \{P_t : t \in [0, \infty)\}$  denote the semigroup of transition matrices of X, so that  $P_t(x, y) = \mathbb{P}(X_t = y \mid X = x)$  for  $(x, y) \in \mathbb{N}^2$ . Similarly, G denotes the infinitesimal generator matrix of X.

The infinitesimal generator G is given by

$$G(x,x)=-lpha x, \hspace{1em} x\in \mathbb{N} \ G(x,x+k-1) = lpha x f(k), \hspace{1em} x\in \mathbb{N}_+, \hspace{1em} k\in \mathbb{N}$$

Proof

This follows immediately from the exponential parameter function and the jump transition matrix above.

The Kolmogorov backward equation is

$$rac{d}{dt}P_t(x,y) = -lpha x P_t(x,x) + lpha x \sum_{k=0}^\infty f(k) P_t(x+k-1,y), \quad (x,y) \in \mathbb{N}^2$$
 (16.23.3)

Proof

The backward equation is  $\frac{d}{dt}P_t = GP_t$ , so the result follows from the previous theorem.

Unlike some of our other continuous-time models, the jump chain Y governed by Q is not the discrete-time version of the model. That is, Y is not a discrete-time branching chain, since in discrete time, the index n represents the nth generation, whereas here it represent the nth time that a particle reproduces. However, there are lots of discrete-time branching chain embedded in the continuous-time chain.

Fix  $t \in (0, \infty)$  and define  $\mathbf{Z}_t = \{X_{nt} : n \in \mathbb{N}\}$ . Then  $\mathbf{Z}_t$  is a discrete-time branching chain with offspring probability density function  $f_t$  given by  $f_t(x) = P_t(1, x)$  for  $x \in \mathbb{N}$ .

Proof

In general, we know that sampling a (homogeneous) continuous-time Markov chain at multiples of a fixed  $t \in (0, \infty)$ , results in a (homogeneous) discrete-time Markov chain. For  $Z_t$  to be a branching chain, we just need to note that

$$P_t(x,y) = f_t^{*x}(y), \quad (x,y) \in \mathbb{N}^2$$
 (16.23.4)

where  $f_t^{*x}$  is the convolution power of  $f_t$  of order x. This is a consequence of the fundamental fact that  $X_t$  given  $X_0 = x$  has the same distribution as the sum of x independent copies of  $X_t$  given  $X_0 = 1$ . Recall that the PDF of a sum of independent variables is the convolution of the individual PDFs.

#### **Probability Generating Functions**

As in the discrete case, probability generating functions are an important analytic tool for continuous-time branching chains.

For  $t \in [0,\infty)$  let  $\Phi_t$  denote the probability generating function of  $X_t$  given  $X_0 = 1$ 

$$\Phi_t(r) = \mathbb{E}\left(r^{X_t} \mid X_0 = 1\right) = \sum_{x=0}^{\infty} r^x P_t(1, x)$$
(16.23.5)

Let  $\Psi$  denote the probability generating function of *N* 

$$\Psi(r) = \mathbb{E}\left(r^{N}\right) = \sum_{n=0}^{\infty} r^{n} f(n)$$
(16.23.6)

The generating functions are defined (the series are absolutely convergent) at least for  $r \in (-1, 1]$ .

The collection of generating functions  $\mathbf{\Phi} = \{ \Phi_t : t \in [0, \infty) \}$  gives the same information as the collection of probability density functions  $\{ P_t(1, \cdot) : t \in [0, \infty) \}$ . With the fundamental insight that the branching process starting with one particle determines the branching process in general,  $\mathbf{\Phi}$  actually determines the transition semigroup  $\mathbf{P} = \{ P_t : t \in [0, \infty) \}$ .

For  $t \in [0, \infty)$  and  $x \in \mathbb{N}$ , the probability generating function of  $X_t$  given  $X_0 = x$  is  $\Phi_t^x$ :

$$\sum_{y=0}^{\infty} r^{y} P_{t}(x,y) = [\Phi_{t}(r)]^{x}$$
(16.23.7)

Proof

Again, given  $X_0 = x$ , the number of particles  $X_t$  at time t has the same distribution as the sum of x independent copies of  $X_t$  given  $X_0 = 1$ . Recall that the PGF of a sum of independent variables is the product of the PGFs of the variables.

Note that  $\Phi_t$  is the generating function of the offspring distribution for the embedded discrete-time branching chain  $Z_t = \{X_{nt} : n \in \mathbb{N}\}$  for  $t \in (0, \infty)$ . On the other hand,  $\Psi$  is the generating function of the offspring distribution for the continuous-time chain. So our main goal in this discussion is to see how  $\Phi$  is built from  $\Psi$ . Because P is a semigroup under matrix multiplication, and because the particles act identically and independently,  $\Phi$  is a semigroup under composition.

$$\Phi_{s+t}=\Phi_s\circ\Phi_t \;\; ext{for}\;s,\;t\in[0,\infty).$$

Proof

Using the semigroup property (the Chapman-Kolmogorov equations) and the previous result we have

$$egin{aligned} \Phi_{s+t}(r) &= \sum_{y=0}^\infty r^y P_{s+t}(1,y) = \sum_{y=0}^\infty r^y \sum_{x=0}^\infty P_s(1,x) P_t(x,y) = \sum_{x=0}^\infty P_s(1,x) \sum_{y=0}^\infty r^y P_t(x,y) \ &= \sum_{x=0}^\infty P_s(1,x) [\Phi_t(r)]^x = \Phi_s[\Phi_t(r)] \end{aligned}$$

Note also that  $\Phi_0(r) = \mathbb{E}(r^{X_0} | X_0 = 1) = r$  for all  $r \in \mathbb{R}$ . This also follows from the semigroup property:  $\Phi_0 = \Phi_0 \circ \Phi_0$ . The fundamental relationship between the collection of generating functions  $\Phi$  and the generating function  $\Psi$  is given in the following theorem:

The mapping  $t\mapsto \Phi_t$  satisfies the differential equation

$$\frac{d}{dt}\Phi_t = \alpha(\Psi \circ \Phi_t - \Phi_t) \tag{16.23.8}$$

Proof

Using the Kolmogorov backward equation we have

$$\frac{d}{dt}\Phi_t(r) = \sum_{x=0}^{\infty} r^x \frac{d}{dt} P_t(1,x) = \sum_{x=0}^{\infty} r^x G P_t(1,x)$$
(16.23.9)

Using the generator above,

$$GP_t(1,x) = \sum_{y=0}^{\infty} G(1,y)P_t(y,x) = -\alpha P_t(1,x) + \sum_{k=0}^{\infty} \alpha f(k)P_t(k,x), \quad x \in \mathbb{N}$$
 (16.23.10)

Substituting and using the result above gives

$$\begin{aligned} \frac{d}{dt}\Phi_t(r) &= \sum_{x=0}^{\infty} r^x \left[ -\alpha P_t(1,x) + \sum_{k=0}^{\infty} \alpha f(k) P_t(k,x) \right] = -\alpha \sum_{x=0}^{\infty} r^x P_t(1,x) + \alpha \sum_{x=0}^{\infty} \sum_{k=0}^{\infty} r^x f(k) P_t(k,x) \\ &= -\alpha \Phi_t(r) + \alpha \sum_{k=0}^{\infty} f(k) \sum_{x=0}^{\infty} r^x P_t(k,x) = -\alpha \Psi_t(r) + \alpha \sum_{k=0}^{\infty} f(k) [\Phi_t(r)]^k = -\alpha \Phi_t(r) + \alpha \Psi[\Phi_t(r)] \end{aligned}$$

This differential equation, along with the initial condition  $\Phi_0(r) = r$  for all  $r \in \mathbb{R}$  determines the collection of generating functions  $\Phi$ . In fact, an implicit solution for  $\Phi_t(r)$  is given by the integral equation

$$\int_{r}^{\Phi_{t}(r)} \frac{1}{\Psi(u) - u} du = \alpha t$$
(16.23.11)

Another relationship is given in the following theorem. Here,  $\Phi'_t$  refers to the derivative of the generating function  $\Phi_t$  with respect to its argument, of course (so *r*, not *t*).

For 
$$t\in [0,\infty)$$

$$\Phi'_t = \frac{\Psi \circ \Phi_t - \Phi_t}{\Psi - \Phi_0} \tag{16.23.12}$$

Proof

From the semigroup property, we have  $\Phi_{t+s}(r) = \Phi_t[\Phi_s(r)]$  for  $s, t \in [0, \infty)$ . Differentiating with respect to s and using the chain rule along with the previous theorem gives

$$\frac{d}{ds}\Phi_{t+s}(r) = \Phi_t'[\Phi_s(r)]\frac{d}{ds}\Phi_s(r) = \Phi_t'[\Phi_s(r)]\alpha \left[\Psi(\Phi_s(r)) - \Phi_s(r)\right]$$
(16.23.13)

Evaluating at s = 0 and using the condition  $\Phi_0(r) = r$  we have

$$\frac{d}{dt}\Phi_t(r) = \Phi'_t(r)\alpha[\Psi(r) - r]$$
(16.23.14)

Using the previous theorem once again gives

$$\alpha \left[ \Psi(\Phi_t(r)) - \Phi_t(r) \right] = \Phi'_t(r) \alpha \left[ \Psi(r) - r \right]$$
(16.23.15)

Solving for  $\Phi'_t(r)$  gives the result.

#### Moments

In this discussion, we will study the mean and variance of the number of particles at time  $t \in [0, \infty)$ . Let

$$m_t = \mathbb{E}(X_t \mid X_0 = 1), \; v_t = \operatorname{var}(X_t \mid X_0 = 1), \quad t \in [0, \infty)$$
 (16.23.16)

so that  $m_t$  and  $v_t$  are the mean and variance, starting with a single particle. As always with a branching process, it suffices to consider a single particle:

$$egin{array}{lll} ext{For}\ t\in [0,\infty)\ ext{and}\ x\in \mathbb{N}, \ 1.\ \mathbb{E}(X_t\mid X_0=x)=x\ m_t \ 2.\ ext{var}(X_t\mid X_0=x)=x\ v_t \end{array}$$

Proof

Once again, the distribution of  $X_t$  given  $X_0 = x$  is the same as the distribution of the sum of x independent copies of  $X_t$  given  $X_0 = 1$ . Recall that the mean of a sum of variables is the sum of the individual means, and the variance of the sum of *independent* variables is the sum of the individual variances.

Recall also that  $\mu$  and  $\sigma^2$  are the mean and variance of the number of offspring of a particle. Here is the connection between the means:

$$\begin{split} m_t &= e^{\alpha(\mu-1)t} \, \text{ for } t \in [0,\infty). \\ 1. \text{ If } \mu &< 1 \, \text{ then } m_t \to 0 \, \text{ as } t \to \infty. \text{ This is extinction in the mean.} \\ 2. \text{ If } \mu &> 1 \, \text{ then } m_t \to \infty \, \text{ as } t \to \infty. \text{ This is explosion in the mean.} \\ 3. \text{ If } \mu &= 1 \, \text{ then } m_t = 1 \, \text{ for all } t \in [0,\infty). \text{ This is stability in the mean.} \end{split}$$

Proof

From the proof of the previous theorem,

$$\frac{d}{dt}\Phi_t(r) = \alpha \Phi_t'(r)[\Psi(r) - r]$$
(16.23.17)

Differentiating with respect to r, interchanging the order of integration on the left, and using the product rule on the right gives

$$\frac{d}{dt}\Phi_t'(r) = \alpha \Phi_t''(r)[\Psi(r) - r] + \alpha \Phi_t'(r)[\Psi'(r) - 1]$$
(16.23.18)

Now let r = 1 and recall that  $\Phi(1) = 1$ . We get

$$\frac{d}{dt}\Phi'_t(1) = \alpha \Phi'_t(1)[\Psi'(1) - 1]$$
(16.23.19)

From the basic theory of probability generating functions,  $m_t = \Phi'_t(1)$  and similarly,  $\mu = \Psi'(1)$ . Hence we have

$$\frac{d}{dt}m_t = \alpha(\mu - 1)m_t \tag{16.23.20}$$

Of course we have the initial condition  $m_0 = 1$  .

This result is intuitively very appealing. As a function of time, the expected number of particles either grows or decays exponentially, depending on whether the expected number of offspring of a particle is greater or less than one. The connection between the variances is more complicated. We assume that  $\sigma^2 < \infty$ .

If  $\mu \neq 1$  then

$$v_t = \left[\frac{\sigma^2}{\mu - 1} + (\mu - 1)\right] \left[e^{2\alpha(\mu - 1)t} - e^{\alpha(\mu - 1)t}\right], \quad t \in [0, \infty)$$
(16.23.21)

If  $\mu = 1$  then  $v_t = \alpha \sigma^2 t$ .

1. If  $\mu < 1$  then  $v_t \to 0$  as  $t \to \infty$ 2. If  $\mu \ge 1$  then  $v_t \to \infty$  as  $t \to \infty$ 

Proof

Probability generating functions are naturally connected to factorial moments, so it's best to work with these. Thus, let  $w_t = \mathbb{E}[X_t(X_t - 1) \mid X_0 = 1]$  for  $t \in [0, \infty)$  and let  $\delta = \mathbb{E}[N(N - 1)]$ . These are the factorial moments of order 2. In the proof of the last theorem we showed that

$$\frac{d}{dt}\Phi_t'(r) = \alpha \Phi_t''(r)[\Psi(r) - r] + \alpha \Phi_t'(r)[\Psi'(r) - 1]$$
(16.23.22)

Differentiating with respect to r again gives

$$\frac{d}{dt}\Phi_t''(r) = \alpha \Phi_t'''(r)[\Psi(r) - r] + 2\alpha \Phi_t''(r)[\Psi'(r) - 1] + \alpha \Phi_t'(r)\Psi''(r)$$
(16.23.23)

Now substitute r = 1. Recall that  $\Phi''_t(1) = w_t$ ,  $\Phi'_t(1) = m_t = e^{\alpha(\mu-1)t}$ ,  $\Psi''(1) = \delta$ ,  $\Psi'(1) = \mu$ , and  $\Psi(1) = 1$ . We get the differential equation

$$\frac{d}{dt}w_t = 2\alpha(\mu - 1)w_t + \alpha\delta e^{\alpha(\mu - 1)t}$$
(16.23.24)

with the initial condition  $w_0 = 0$ .

Suppose that  $\mu \neq 1$ . Then using standard methods for a linear, first order differential equations with constant coefficients and an exponential forcing function, the solution is

$$w_t = \frac{\delta}{\mu - 1} \left[ e^{2\alpha(\mu - 1)} - e^{\alpha(\mu - 1)t} \right]$$
(16.23.25)

But  $\delta = \sigma^2 + \mu^2 - \mu$ , and similarly  $w_t = v_t + m_t^2 - m_t$  with  $m_t = e^{\alpha(\mu - 1)t}$ . Substitution and some algebra then gives the result.

Suppose now that  $\mu = 1$ . Then also  $m_t = 1$  for all  $t \in [0, \infty)$  and so  $\delta = \sigma^2$  and  $v_t = w_t$ . The differential equation above reduces simply to

$$\frac{d}{dt}v_t = \alpha\sigma^2 \tag{16.23.26}$$

with initial condition  $v_0 = 0$  so trivially  $v_t = \alpha \sigma^2 t$ . Finally, in the context of part (b), note that if  $\mu = 1$  we must have  $\sigma^2 > 0$  since we have assumed that f(1) = 0.

If  $\mu < 1$  so that  $m_t \to 0$  as  $t \to \infty$  and we have extinction in the mean, then  $v_t \to 0$  as  $t \to \infty$  also. If  $\mu > 1$  so that  $m_t \to \infty$  as  $t \to \infty$  and we have explosion in the mean, then  $v_t \to \infty$  as  $t \to \infty$  also. We would expect these results. On the other hand, if  $\mu = 1$  so that  $m_t = 1$  for all  $t \in [0, \infty)$  and we have stability in the mean, then  $v_t$  grows linearly in t. This gives some insight into what to expect next when we consider the *probability* of extinction.

#### The Probability of Extinction

As shown above, there are two types of behavior for a branching process, either population extinction or population explosion. In this discussion, we study the extinction probability, starting as usual with a single particle:

$$q = \mathbb{P}(X_t = 0 \text{ for some } t \in (0, \infty) \mid X_0 = 1) = \lim_{t \to \infty} \mathbb{P}(X_t = 0 \mid X_0 = 1)$$
(16.23.27)

Need we say it? The extinction probability starting with an arbitrary number of particles is easy.

For  $x \in \mathbb{N}$ ,

$$\mathbb{P}(X_t = 0 \text{ for some } t \in (0,\infty) \mid X_0 = x) = \lim_{t \to \infty} \mathbb{P}(X_t = 0 \mid X_0 = x) = q^x \tag{16.23.28}$$

Proof

Given  $X_0 = x$ , extinction has occurred by time *t* if and only if extinction has occurred by time *t* for each of the *x* independent branching chains formed from the descendents of the *x* initial particles.

We can easily relate extinction for the continuous-time branching chain X to extinction for any of the embedded discrete-time branching chains.

If extinction occurs for X then extinction occurs for  $Z_t$  for every  $t \in (0, \infty)$ . Conversely if extinction occurs for  $Z_t$  for some  $t \in (0, \infty)$  then extinction occurs for  $Z_t$  for every  $t \in (0, \infty)$  and extinction occurs for X. Hence q is the minimum solution in (0, 1] of the equation  $\Phi_t(r) = r$  for every  $t \in (0, \infty)$ .

Proof

The statements about the extinction event follow immediately from the fact that 0 is absorbing, so that if  $X_t = 0$  for some  $t \in (0, \infty)$  then  $X_s = 0$  for every  $s \in [t, \infty)$ . The result for the extinction probability q follows from the theory of discrete-time branching chains.

So whether or not extinction is certain depends on the critical parameter  $\mu$ .

The extinction probability q and the mean of the offspring distribution  $\mu$  are related as follows:

1. If  $\mu \leq 1$  then q = 1, so extinction is certain.

2. If  $\mu > 1$  then 0 < q < 1, so there is a positive probability of extinction and a positive probability of explosion.

#### Proof

These results follow from the corresponding results for discrete-time branching chains. Fix  $t \in (0, \infty)$  and recall that  $m_t$  is the mean of the offspring distribution for the discrete-time chain  $\mathbf{Z}_t = \{X_{nt} : n \in \mathbb{N}\}$ . From the result above,

1. If  $\mu \leq 1$  then  $m_t \leq 1$ . 2. If  $\mu > 1$  then  $m_t > 1$ .

It would be nice to have an equation for q in terms of the offspring probability generating function  $\Psi$ . This is also easy

The probability of extinction *q* is the minimum solution in (0, 1] of the equation  $\Psi(r) = r$ .

Proof

From the result above,  $\Phi_t(q) = 1$  for every  $t \in (0, \infty)$ . Substituting r = q in the differential equation above, we have  $\frac{d}{dt}\Phi_t(q) = 0$  and hence  $\Psi(q) = q$ . As in the theory of discrete branching chains, the equation  $\Psi(r) = r$  has only the solution 1 in (0, 1] if  $\mu = \Psi'(1) \leq 1$  or there are two solutions  $q \in (0, 1)$  and 1 if  $\mu > 0$ . In both cases, q is the smaller solution.

#### Special Models

We now turn our attention to a number of special branching chains that are important in applications or lead to interesting insights. We will use the notation established above, so that  $\alpha$  is the parameter of the exponential lifetime of a particle, Q is the transition matrix of the

jump chain, *G* is the infinitesimal generator matrix, and  $P_t$  is the transition matrix at time  $t \in [0, \infty)$ . Similarly,  $m_t = \mathbb{E}(X_t \mid X_0 = x)$ ,  $v_t = var(X_t \mid X_0 = x)$ , and  $\Phi_t$  are the mean, variance, and generating function of the number of particles at time  $t \in [0, \infty)$ , starting with a single particle. As always, be sure to try these exercises yourself before looking at the proofs and solutions.

#### The Pure Death Branching Chain

First we consider the branching chain in which each particle simply dies without offspring. Sadly for these particles, extinction is inevitable, but this case is still a good place to start because the analysis is simple and lead to explicit formulas. Thus, suppose that  $X = \{X_t : t \in [0, \infty)\}$  is a branching process with lifetime parameter  $\alpha \in (0, \infty)$  and offspring probability density function f with f(0) = 1.

The transition matrix of the jump chain and the generator matrix are given by

 $egin{aligned} 1.\ Q(0,0) = 1 ext{ and } Q(x,x-1) = 1 ext{ for } x \in \mathbb{N}_+ \ 2.\ G(x,x) = -lpha x ext{ for } x \in \mathbb{N} ext{ and } G(x,x-1) = lpha x ext{ for } x \in \mathbb{N}_+ \end{aligned}$ 

The time-varying functions are more interesting.

Let  $t \in [0, \infty)$ . Then 1.  $m_t = e^{-\alpha t}$ 2.  $v_t = e^{-\alpha t} - e^{-2\alpha t}$ 3.  $\Phi_t(r) = 1 - (1 - r)e^{-\alpha t}$  for  $r \in \mathbb{R}$ 4. Given  $X_0 = x$  the distribution of  $X_t$  is binomial with trial parameter x and success parameter  $e^{-\alpha t}$ .

$$P_t(x,y) = {x \choose y} e^{-lpha t y} (1-e^{-lpha t})^{x-y}, \quad x \in \mathbb{N}, \ y \in \{0,1,\ldots,x\}$$
 (16.23.29)

Direct Proof

All of these results follow from the general methods above, with  $\mu = \sigma = 0$  and  $\Psi(r) = 1$  for  $r \in \mathbb{R}$ . But it's helpful to give direct proofs. Given  $X_0 = 1$ , let  $\tau$  be the time until the first transition, which is simply the lifetime of the particle. So  $\tau$  has the exponential distribution with parameter  $\alpha$ . For  $t \in [0, \infty)$ ,  $X_t$  is an indicator random variable (taking just values 0 and 1) with

$$\mathbb{P}(X_t = 1 \mid X_0 = 1) = \mathbb{P}(\tau > t \mid X_0 = 1) = e^{-\alpha t}$$
(16.23.30)

Part (a), (b), and (c) are standard results for an indicator variable. For part (d), given  $X_0 = x$ , each of the x particles, independently, is still alive at time t with probability  $e^{-\alpha t}$ . Hence the number of particles still alive has the binomial distribution with parameters x and  $e^{-\alpha t}$ .

In particular, note that  $P_t(x, 0) = (1 - e^{-\alpha t})^x \to 1$  as  $t \to \infty$ . that is, the probability of extinction by time t increases to 1 exponentially fast. Since we have an explicit formula for the transition matrices, we can find an explicit formula for the potential matrices as well. The result uses the beta function B.

For  $\beta \in (0,\infty)$  the potential matrix  $U_{\beta}$  is given by

$$U_eta(x,y)=rac{1}{lpha}inom{x}{y}B(y+eta/lpha,x-y+1), \quad x\in\mathbb{N},\,y\in\{0,1,\ldots,x\}$$

For  $\beta = 0$ , the potential matrix U is given by

 $egin{aligned} 1.\ U(x,0) &= \infty ext{ for } x \in \mathbb{N} \ 2.\ U(x,y) &= 1/lpha y ext{ for } x, \ y \in \mathbb{N}_+ ext{ and } x \leq y. \end{aligned}$ 

Proof

Suppose that eta > 0 and that  $x, \ y \in \mathbb{N}$  with  $x \leq y$  . By definition

$$U_{\beta}(x,y) = \int_{0}^{\infty} e^{-\beta t} P_{t}(x,y) dt = \int_{0}^{\infty} e^{-\beta t} {x \choose y} e^{-\alpha t y} (1 - e^{-\alpha t})^{x-y} dt$$
(16.23.32)

Substitute  $u = e^{-\alpha t}$  so that  $du = -\alpha e^{-\alpha t} dt$  or equivalently  $dt = -du/\alpha u$ . After some algebra, the result is

$$U_{\beta}(x,y) = \frac{1}{\alpha} \binom{x}{y} \int_{0}^{1} u^{y+\beta/\alpha-1} (1-u)^{x-y} du$$
(16.23.33)

By definition, the last integral is B(y+eta/lpha,x-y+1) .

1. For  $x\in\mathbb{N}$  ,

$$U(x,0) = \int_0^\infty (1 - e^{-\alpha t})^x dd = \infty$$
 (16.23.34)

2. For  $x, y \in \mathbb{N}_+$  with  $x \leq y$ , the derivation above and properties of the beta function give

$$U(x,y) = \frac{1}{\alpha} \binom{x}{y} B(y,x-y+1) = \frac{1}{\alpha} \binom{x}{y} \frac{(y-1)!(x-y)!}{x!} = \frac{1}{\alpha y}$$
(16.23.35)

We could argue the results for the potential U directly. Recall that U(x, y) is the expected time spent in state y starting in state x. Since 0 is absorbing and all states lead to 0,  $U(x, 0) = \infty$  for  $x \in \mathbb{N}$ . If  $x, y \in \mathbb{N}_+$  and  $x \leq y$ , then x leads to y with probability 1. Once in state y the time spent in y has an exponential distribution with parameter  $\lambda(y) = \alpha y$ , and so the mean is  $1/\alpha y$ . Of course, when the chain leaves y, it never returns.

Recall that  $\beta U_{\beta}$  is a transition probability matrix for  $\beta > 0$ , and in fact  $\beta U_{\beta}(x, \cdot)$  is the probability density function of  $X_T$  given  $X_0 = x$  where T is independent of X has the exponential distribution with parameter  $\beta$ . For the next result, recall the *ascending power* notation

 $a^{[k]} = a(a+1)\cdots(a+k-1), \quad a \in \mathbb{R}, \ k \in \mathbb{N}$  (16.23.36)

For  $\beta > 0$  and  $x \in \mathbb{N}_+$ , the function  $\beta U_{\beta}(x, \cdot)$  is the beta-binomial probability density function with parameters  $x, \beta/\alpha$ , and 1.

$$eta U_eta(x,y) = inom{x}{y} rac{(eta/lpha)^{|y|} 1^{|x-y|}}{(1+eta/lpha)^{[x]}}, \quad x \in \mathbb{N}, \, y \in \{0,1,\dots x\}$$
(16.23.37)

Proof

From the previous result and properties of the beta function.

$$eta U_eta(x,y) = rac{eta}{lpha} inom{x}{y} B(y+eta/lpha,x-y+1), \quad x\in\mathbb{N},\,y\in\{0,1,\ldots,x\}$$
(16.23.38)

But from properties of the beta function,

$$B(y+\beta/\alpha, x-y+1) = B(\beta/\alpha, 1) \frac{(\beta/\alpha)^{[y]} 1^{[x-y]}}{(1+\beta/\alpha)^{[x]}} = \frac{\alpha}{\beta} \frac{(\beta/\alpha)^{[y]} 1^{[x-y]}}{(1+\beta/\alpha)^{[x]}}$$
(16.23.39)

Substituting gives the result

## The Yule Process

Next we consider the pure birth branching chain in which each particle, at the end of its life, is replaced by 2 new particles. Equivalently, we can think of particles that never die, but each particle gives birth to a new particle at a constant rate. This chain could serve as the model for an unconstrained nuclear reaction, and is known as the *Yule process*, named for George Yule. So specifically, let  $X = \{X_t : t \in [0, \infty)\}$  be the branching chain with exponential parameter  $\alpha \in (0, \infty)$  and offspring probability density function given by f(2) = 1. Explosion is inevitable, starting with at least one particle, but other properties of the Yule process are interesting. in particular, there are fascinating parallels with the pure death branching chain. Since 0 is an isolated, absorbing state, we will sometimes restrict our attention to positive states.

The transition matrix of the jump chain and the generator matrix are given by

 $egin{aligned} 1.\ Q(0,0) = 1 ext{ and } Q(x,x+1) = 1 ext{ for } x \in \mathbb{N}_+ \ 2.\ G(x,x) = -lpha x ext{ for } x \in \mathbb{N} ext{ and } G(x,x+1) = lpha x ext{ for } x \in \mathbb{N}_+ \end{aligned}$ 

Since the Yule process is a pure birth process and the birth rate in state  $x \in \mathbb{N}$  is  $\alpha x$ , the process is also called the *linear birth chain*. As with the pure death process, we can give the distribution of  $X_t$  specifically.

Let 
$$t \in [0, \infty)$$
. Then  
1.  $m_t = e^{\alpha t}$   
2.  $v_t = e^{2\alpha t} - e^{\alpha t}$   
3.  $\Phi_t(r) = \frac{re^{-\alpha t}}{1 - r + re^{-\alpha t}}$  for  $|r| < \frac{1}{1 - e^{-\alpha t}}$ 

4. Given  $X_0 = x$ ,  $X_t$  has the negative binomial distribution on  $\mathbb{N}_+$  with stopping parameter x and success parameter  $e^{-\alpha t}$ .

$$P_t(x,y) = \binom{y-1}{x-1} e^{-x\alpha t} (1-e^{-\alpha t})^{y-x}, \quad x \in \mathbb{N}_+, \ y \in \{x,x+1,\ldots\}$$
(16.23.40)

Proof from the general results

Parts (a) and (b) follow from the general moment results above, with  $\mu = 2$  and  $\sigma^2 = 0$ . For part (c), note that  $\Psi(r) = r^2$  for  $r \in \mathbb{R}$ , so the integral equation for  $\Phi_t$  is

$$\int_{r}^{\Phi_{t}(r)} \frac{1}{u^{2} - u} = \alpha t \tag{16.23.41}$$

From partial fractions,  $\frac{1}{u^2-u} = \frac{1}{u-1} - \frac{1}{u}$ , so the result follows by standard integration and algebra. We recognize  $\Phi_t$  as the probability generating function of the geometric distribution on  $\mathbb{N}_+$  with success parameter  $e^{-\alpha t}$ , so for part (d) we use our standard argument. Given  $X_0 = x \in \mathbb{N}_+$ ,  $X_t$  has the same distribution as the sum of x independent copies of  $X_t$  given  $X_0 = 1$ , and so this is the distribution of the sum of x independent variables each with the geometric distribution on  $\mathbb{N}_+$  with parameter  $e^{-\alpha t}$ . But this is the negative binomial distribution on  $\mathbb{N}_+$  with parameters x and  $e^{-\alpha t}$ .

#### Direct proof

As usual, let  $\tau_0 = 0$  and let  $\tau_n$  denote the time of the *n*th transition (birth) for  $n \in \mathbb{N}_+$ . Given  $X_0 = 1$ , the population is *n* at time  $\tau_{n-1}$ . So the random interval  $\tau_n - \tau_{n-1}$  (the time until the next birth) has the exponential distribution with parameter  $\alpha n$  and these intervals are independent as *n* varies. From a result in the section on the exponential distribution, it follows that  $\tau_n = \sum_{k=1}^n (\tau_k - \tau_{k-1})$  has distribution function given by

$$\mathbb{P}(\tau_n \le t \mid X_0 = 1) = (1 - e^{-\alpha t})^n, \quad t \in [0, \infty)$$
(16.23.42)

Curiously, this is also the distribution function of the maximum of n independent variables, each with the exponential distribution with rate  $\alpha$ . Hence

$$\mathbb{P}(X_t \ge n \mid X_0 = 1) = \mathbb{P}(\tau_{n-1} \le t \mid X_0 = 1) = (1 - e^{-\alpha t})^{n-1}, \quad n \in \mathbb{N}_+$$
(16.23.43)

and therefore

$$\mathbb{P}(X_t = n \mid X_0 = 1) = \mathbb{P}(X_t \ge n \mid X_0 = 1) - \mathbb{P}(X_t \ge n + 1 \mid X_0 = 1) = (1 - e^{-\alpha t})^{n-1} e^{-\alpha t}, \quad n \in \mathbb{N}_+ \quad (16.23.44)$$

So given  $X_0 = 1$ ,  $X_t$  has the geometric distribution with parameter  $e^{-\alpha t}$ . The other results then follow easily.

Recall that the negative binomial distribution with parameters  $k \in \mathbb{N}_+$  and  $p \in (0, 1)$  governs the trial number of the *k*th success in a sequence of Bernoulli trials with success parameter *p*. So the occurrence of this distribution in the Yule process suggests such an interpretation. However this interpretation is not nearly as obvious as with the binomial distribution in the pure death branching chain. Next we give the potential matrices.

For  $\beta \in [0, \infty)$  the potential matrix  $U_{\beta}$  is given by

$$U_{eta}(x,y) = rac{1}{lpha}igg( rac{y-1}{x-1}igg) B(x+eta/lpha,y-x+1), \quad x\in\mathbb{N}_+,\,y\in\{x,x+1,\ldots\}$$
(16.23.45)

If  $\beta > 0$ , the function  $\beta U_{\beta}(x, \cdot)$  is the beta-negative binomial probability density function with parameters  $x, \beta/\alpha$ , and 1:

$$eta U_eta(x,y) = inom{y-1}{x-1} rac{(eta/lpha)^{[x]} 1^{[y-x]}}{(1+eta/lpha)^{[y]}}, \quad x \in \mathbb{N}, \, y \in \{x,x+1,\ldots\}$$
(16.23.46)

Proof

The proof is very similar to the one above. Suppose that  $\beta \ge 0$  and that  $x, y \in \mathbb{N}_+$  with  $y \ge x$ . By definition

$$U_{\beta}(x,y) = \int_{0}^{\infty} e^{-\beta t} P_{t}(x,y) dt = \int_{0}^{\infty} e^{-\beta t} \binom{y-1}{x-1} e^{-\alpha tx} (1-e^{-\alpha t})^{y-x} dt$$
(16.23.47)

Substitute  $u = e^{-\alpha t}$  so that  $du = -\alpha e^{-\alpha t} dt$  or equivalently  $dt = -du/\alpha u$ . After some algebra, the result is

$$U_{\beta}(x,y) = \frac{1}{\alpha} \binom{y-1}{x-1} \int_{0}^{1} u^{x+\beta/\alpha-1} (1-u)^{y-x} du$$
(16.23.48)

### By definition, the last integral is B(x+eta/lpha,y-x+1) .

If we think of the Yule process in terms of particles that never die, but each particle gives birth to a new particle at rate  $\alpha$ , then we can study the *age* of the particles at a given time. As usual, we can start with a single, new particle at time 0. So to set up the notation, let  $X = \{X_t : t \in [0, \infty)\}$  be the Yule branching chain with birth rate  $\alpha \in (0, \infty)$ , and assume that  $X_0 = 1$ . Let  $\tau_0 = 0$  and for  $n \in \mathbb{N}_+$ , let  $\tau_n$  denote the time of the *n*th transition (birth).

For  $t \in [0, \infty)$ , let  $A_t$  denote the total age of the particles at time t. Then

$$A_t = \sum_{n=0}^{X_t-1} (t- au_n), \quad t \in [0,\infty)$$
 (16.23.49)

The random process  $oldsymbol{A} = \{A_t: t \in [0,\infty)\}$  is the *age process*.

Proof

Note that there have been  $X_t - 1$  births in the interval [0, t]. For  $n \in \{0, 1, ..., X_t - 1\}$ , the age at time t of the particle born at time  $\tau_n$  is  $t - \tau_n$ .

Here is another expression for the age process.

Again, let  $A = \{A_t : t \in [0, \infty)\}$  be the age process for the Yule chain starting with a single particle. Then

$$A_t = \int_0^t X_s ds, \quad t \in [0,\infty)$$
 (16.23.50)

Proof

Suppose that  $X_t = k+1$  where  $k \in \mathbb{N}$ , so that  $\tau_k \leq t < \tau_{k+1}$ . Note that  $X_s = n$  for  $\tau_{n-1} \leq s < \tau_n$  and  $n \in \{1, 2, \dots, k\}$ , while  $X_s = k+1$  for  $\tau_k \leq s \leq t$ . Hence

$$\int_{0}^{t} X_{s} ds = \sum_{n=1}^{k} n(\tau_{n} - \tau_{n-1}) + (k+1)(t - \tau_{k}) = (k+1)t - \sum_{n=0}^{k} \tau_{n}$$
(16.23.51)

From the previous result,

$$A_t = \sum_{n=0}^{k} (t - \tau_n) = (k+1)t - \sum_{n=0}^{k} \tau_n$$
(16.23.52)

With the last representation, we can easily find the expected total age at time t.

Again, let  $A = \{A_t : t \in [0, \infty)\}$  be the age process for the Yule chain starting with a single particle. Then

$$\mathbb{E}(A_t)=rac{e^{lpha t}-1}{lpha},\quad t\in[0,\infty)$$
(16.23.53)

Proof

We can interchange the expected value and the integral by Fubini's theorem. So using the moment result above,

$$\mathbb{E}(A_t) = \mathbb{E}\left(\int_0^t X_s ds\right) = \int_0^t \mathbb{E}(X_s) ds = \int_0^t e^{\alpha s} ds = \frac{e^{\alpha t} - 1}{\alpha}$$
(16.23.54)

#### The General Birth-Death Branching Chain

Next we consider the continuous-time branching chain in which each particle, at the end of its life, leaves either no children or two children. At each transition, the number of particles either increases by 1 or decreases by 1, and so such a branching chain is also a continuous-time birth-death chain. Specifically, let  $X = \{X_t : t \in [0, \infty)\}$  be a continuous-time branching chain with lifetime parameter  $\alpha \in (0, \infty)$  and offspring probability density function f given by f(0) = 1 - p, f(2) = p, where  $p \in [0, 1]$ . When p = 0 we have the pure death chain, and when p = 1 we have the Yule process. We have already studied these, so the interesting case is when  $p \in (0, 1)$  so that both extinction and explosion are possible.

The transition matrix of the jump chain and the generator matrix are given by

1. 
$$Q(0,0)=1$$
, and  $Q(x,x-1)=1-p$ ,  $Q(x,x+1)=p$  for  $x\in\mathbb{N}_+$   
2.  $G(x,x)=-lpha x$  for  $x\in\mathbb{N}$ , and  $G(x,x-1)=lpha(1-p)x$ ,  $G(x,x+1)=lpha px$  for  $x\in\mathbb{N}_+$ 

As mentioned earlier, X is also a continuous-time birth-death chain on  $\mathbb{N}$ , with 0 absorbing. In state  $x \in \mathbb{N}_+$ , the birth rate is  $\alpha px$  and the death rate is  $\alpha(1-p)x$ . The moment functions are given next.

For 
$$t \in [0, \infty)$$
,  
1.  $m_t = e^{\alpha(2p-1)t}$   
2. If  $p \neq \frac{1}{2}$ ,  
 $v_t = \left[\frac{4p(1-p)}{2p-1} + (2p-1)\right] \left[e^{2\alpha(2p-1)t} - e^{\alpha(2p-1)t}\right]$ 
(16.23.55)  
If  $p = \frac{1}{2}$ ,  $v_t = 4\alpha p(1-p)t$ .

Proof

These results follow from the general formulas above for  $m_t$  and  $v_t$ , since  $\mu=2p$  and  $\sigma^2=4p(1-p)$  .

The next result gives the generating function of the offspring distribution and the extinction probability.

For the birth-death branching chain,

1.  $\Psi(r) = pr^2 + (1-p)$  for  $r \in \mathbb{R}$ . 2. q = 1 if  $0 and <math>q = \frac{1-p}{p}$  if  $\frac{1}{2} .$ Proof

Figure 16.23.2 Graphs of  $r \mapsto \Psi(r)$  and  $r \mapsto r$  when  $p = \frac{2}{3}$ 

For  $t \in [0, \infty)$ , the generating function  $\Phi_t$  is given by

$$egin{aligned} \Phi_t(r) &= rac{pr-(1-p)+(1-p)(1-r)e^{lpha(2p-1)t}}{pr-(1-p)+p(1-r)e^{lpha(2p-1)t}}, & ext{if} \ p
eq 1/2 \ \Phi_t(r) &= rac{2r+(1-r)lpha t}{2+(1-r)lpha t}, & ext{if} \ p &= rac{1}{2} \end{aligned}$$

Solution

The integral equation for  $\Phi_t$  is

$$\int_{r}^{\Phi_{t}(r)} \frac{du}{pu^{2} + (1-p) - u} = \alpha t$$
(16.23.56)

The denominator in the integral factors into (u-1)[pu-(1-p)]. If  $p \neq \frac{1}{2}$ , use partial fractions, standard integration, and some algebra. If  $p = \frac{1}{2}$  the factoring is  $\frac{1}{2}(u-1)^2$  and partial fractions is not necessary. Again, use standard integration and algebra.

# **CHAPTER OVERVIEW**

## **17: Martingales**

*Martingalges*, and their cousins *sub-martingales* and *super-martingales* are real-valued stochastic processes that are abstract generalizations of fair, favorable, and unfair gambling processes. The importance of martingales extends far beyond gambling, and indeed these random processes are among the most important in probability theory, with an incredible number and diversity of applications.

## 17.1: Introduction to Martingalges

## **Basic Theory**

#### **Basic Assumptions**

For our basic ingredients, we start with a stochastic process  $\mathbf{X} = \{X_t : t \in T\}$  on an underlying probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ , having state space  $\mathbb{R}$ , and where the index set T (representing time) is either  $\mathbb{N}$  (discrete time) or  $[0, \infty)$  (continuous time). So to review what all this means,  $\Omega$  is the sample space,  $\mathscr{F}$  the  $\sigma$ -algebra of events,  $\mathbb{P}$  the probability measure on  $(\Omega, \mathscr{F})$ , and  $X_t$  is a random variable with values in  $\mathbb{R}$  for each  $t \in T$ . Next, we have a filtration  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$ , and we assume that  $\mathbf{X}$  is *adapted* to  $\mathfrak{F}$ . To review again,  $\mathfrak{F}$  is an increasing family of sub  $\sigma$ -algebras of  $\mathscr{F}$ , so that  $\mathscr{F}_s \subseteq \mathscr{F}_t \subseteq \mathscr{F}$  for  $s, t \in T$  with  $s \leq t$ , and  $X_t$  is measurable with respect to  $\mathscr{F}_t$  for  $t \in T$ . We think of  $\mathscr{F}_t$  as the collection of events up to time  $t \in T$ , thus encoding the information available at time t. Finally, we assume that  $\mathbb{E}(|X_t|) < \infty$ , so that the mean of  $X_t$  exists as a real number, for each  $t \in T$ .

There are two important special cases of the basic setup. The simplest case, of course, is when  $\mathscr{F}_t = \sigma\{X_s : s \in T, s \leq t\}$  for  $t \in T$ , so that  $\mathfrak{F}$  is the *natural filtration* associated with X. Another case that arises frequently is when we have a second stochastic process  $Y = \{Y_t : t \in T\}$  on  $(\Omega, \mathscr{F}, \mathbb{P})$  with values in a general measure space  $(S, \mathscr{S})$ , and  $\mathfrak{F}$  is the natural filtration associated with Y. So in this case, our main assumption is that  $X_t$  is measurable with respect to  $\sigma\{Y_s : s \in T, s \leq t\}$  for  $t \in T$ .

The theory of martingales is beautiful, elegant, and mostly accessible in discrete time, when  $T = \mathbb{N}$ . But as with the theory of Markov processes, martingale theory is technically much more complicated in continuous time, when  $T = [0, \infty)$ . In this case, additional assumptions about the continuity of the sample paths  $t \mapsto X_t$  and the filtration  $t \mapsto \mathscr{F}_t$  are often necessary in order to have a nice theory. Specifically, we will assume that the process X is right continuous and has left limits, and that the filtration  $\mathfrak{F}$  is right continuous and complete. These are the *standard assumptions* in continuous time.

#### Definitions

For the basic definitions that follow, you may need to review conditional expected value with respect to a  $\sigma$ -algebra.

The process X is a *martingale* with respect to  $\mathfrak{F}$  if  $\mathbb{E}(X_t \mid \mathscr{F}_s) = X_s$  for all  $s, t \in T$  with  $s \leq t$ .

In the special case that  $\mathfrak{F}$  is the natural filtration associated with X, we simply say that X is a martingale, without reference to the filtration. In the special case that we have a second stochastic process  $Y = \{Y_t : t \in T\}$  and  $\mathfrak{F}$  is the natural filtration associated with Y, we say that X is a martingale with respect to Y.

The term *martingale* originally referred to a portion of the harness of a horse, and was later used to describe gambling strategies, such as the one used in the Petersburg paradox, in which bets are doubled when a game is lost. To interpret the definitions above in terms of gambling, suppose that a gambler is at a casino, and that  $X_t$  represents her fortune at time  $t \in T$  and  $\mathscr{F}_t$  the information available to her at time t. Suppose now that  $s, t \in T$  with s < t and that we think of s as the current time, so that t is a future time. If X is a martingale with respect to  $\mathfrak{F}$  then the games are fair in the sense that the gambler's expected fortune at the future time t is the same as her current fortune at time s. To venture a bit from the casino, suppose that  $X_t$  is the price of a stock, or the value of a stock index, at time  $t \in T$ . If X is a martingale, then the expected value at a future time, given all of our information, is the present value.

Figure 17.1.1: An English-style breastplate with a running martingale attachement. By Danielle M., CC BY 3.0, from Wikipedia

But as we will see, martingales are useful in probability far beyond the application to gambling and even far beyond financial applications generally. Indeed, martingales are of fundamental importance in modern probability theory. Here are two related definitions, with equality in the martingale condition replaced by inequalities.

Suppose again that the process X and the filtration  $\mathfrak{F}$  satisfy the basic assumptions above.

1. **X** is a *sub-martingale* with respect to  $\mathfrak{F}$  if  $\mathbb{E}(X_t \mid \mathscr{F}_s) \ge X_s$  for all  $s, t \in T$  with  $s \le t$ .

### 2. **X** is a *super-martingale* with respect to $\mathfrak{F}$ if $\mathbb{E}(X_t \mid \mathscr{F}_s) \leq X_s$ for all $s, t \in T$ with $s \leq t$ .

In the gambling setting, a sub-martingale models games that are favorable to the gambler on average, while a super-martingale models games that are unfavorable to the gambler on average. To venture again from the casino, suppose that  $X_t$  is the price of a stock, or the value of a stock index, at time  $t \in T$ . If X is a sub-martingale, the expected value at a future time, given all of our information, is greater than the present value, and if X is a super-martingale then the expected value at the future time is less than the present value. One hopes that a stock index is a sub-martingale.

Clearly X is a martingale with respect to  $\mathfrak{F}$  if and only if it is both a sub-martingale and a super-martingale. Finally, recall that the conditional expected value of a random variable with respect to a  $\sigma$ -algebra is itself a random variable, and so the equations and inequalities in the definitions should be interpreted as holding with probability 1. In this section generally, statements involving random variables are assumed to hold with probability 1.

The conditions that define martingale, sub-martingale, and super-martingale make sense if the index set T is any totally ordered set. In some applications that we will consider later,  $T = \{0, 1, ..., n\}$  for fixed  $n \in \mathbb{N}_+$ . In the section on backwards martingales,  $T = \{-n : n \in \mathbb{N}\}$  or  $T = (-\infty, 0]$ . In the case of discrete time when  $T = \mathbb{N}$ , we can simplify the definitions slightly.

Suppose that  $X = \{X_n : n \in \mathbb{N}\}$  satisfies the basic assumptions above.

- 1. **X** is a martingale with respect to  $\mathfrak{F}$  if and only if  $\mathbb{E}(X_{n+1} \mid \mathscr{F}_n) = X_n$  for all  $n \in \mathbb{N}$ .
- 2. **X** is a sub-martingale with respect to  $\mathfrak{F}$  if and only if  $\mathbb{E}(X_{n+1} \mid \mathscr{F}_n) \geq X_n$  for all  $n \in \mathbb{N}$ .
- 3. **X** is a super-martingale with respect to  $\mathfrak{F}$  if and only if  $\mathbb{E}(X_{n+1} \mid \mathscr{F}_n) \leq X_n$  for all  $n \in \mathbb{N}$ .

Proof

The conditions in the definitions clearly imply the conditions here, so we just need to show the opposite implications. Thus, assume that the condition in (a) holds and suppose that  $k, n \in \mathbb{N}$  with k < n. Then  $k \leq n-1$  so  $\mathscr{F}_k \subseteq \mathscr{F}_{n-1}$  and hence

$$\mathbb{E}\left(X_{n} \mid \mathscr{F}_{k}\right) = \mathbb{E}\left[\mathbb{E}\left(X_{n} \mid \mathscr{F}_{n-1}\right) \mid \mathscr{F}_{k}\right] = \mathbb{E}\left(X_{n-1} \mid \mathscr{F}_{k}\right)$$
(17.1.1)

Repeating the argument, we get to

$$\mathbb{E}\left(X_{n} \mid \mathscr{F}_{k}\right) = \mathbb{E}\left(X_{k+1} \mid \mathscr{F}_{k}\right) = X_{k} \tag{17.1.2}$$

The proof for sub and super-martingales is analogous, with inequalities replacing the last equality.

The relations that define martingales, sub-martingales, and super-martingales hold for the ordinary (unconditional) expected values.

Suppose that  $s, t \in T$  with  $s \leq t$  .

1. If **X** is a martingale with respect to  $\mathfrak{F}$  then  $\mathbb{E}(X_s) = \mathbb{E}(X_t)$ .

2. If **X** is a sub-martingale with respect to  $\mathfrak{F}$  then  $\mathbb{E}(X_s) \leq \mathbb{E}(X_t)$ .

3. If **X** is a super-martingale with respect to  $\mathfrak{F}$  then  $\mathbb{E}(X_s) \ge \mathbb{E}(X_t)$ .

Proof

The results follow directly from the definitions, and the critical fact that  $\mathbb{E}\left[\mathbb{E}\left(X_{t} \mid \mathscr{P}_{s}\right)\right] = \mathbb{E}(X_{t})$  for  $s, t \in T$ .

So if X is a martingale then X has constant expected value, and this value is referred to as the mean of X.

#### **Examples**

The goal for the remainder of this section is to give some classical examples of martingales, and by doing so, to show the wide variety of applications in which martingales occur. We will return to many of these examples in subsequent sections. Without further ado, we assume that all random variables are real-valued, unless otherwise specified, and that all expected values mentioned below exist in  $\mathbb{R}$ . Be sure to try the proofs yourself before expanding the ones in the text.

#### **Constant Sequence**

Our first example is rather trivial, but still worth noting.

```
Suppose that \mathfrak{F} = \{\mathscr{F}_t : t \in T\} is a filtration on the probability space (\Omega, \mathscr{F}, \mathbb{P}) and that X is a random variable that is measurable with respect to \mathscr{F}_0 and satisfies \mathbb{E}(|X|) < \infty. Let X_t = X for t \in T. Them X = \{X_t : t \in T\} is a martingale with respect to \mathfrak{F}.
Proof
```

Since *X* is measurable with respect to  $\mathscr{F}_0$ , it is measurable with respect to  $\mathscr{F}_t$  for all  $t \in T$ . Hence *X* is adapted to  $\mathfrak{F}$ . If  $s, t \in T$  with  $s \leq t$ , then  $\mathbb{E}(X_t \mid \mathscr{F}_s) = \mathbb{E}(X \mid \mathscr{F}_s) = X = X_s$ .

#### Partial Sums

For our next discussion, we start with one of the most basic martingales in discrete time, and the one with the simplest interpretation in terms of gambling. Suppose that  $V = \{V_n : n \in \mathbb{N}\}$  is a sequence of independent random variables with  $\mathbb{E}(|V_k|) < \infty$  for  $k \in \mathbb{N}$ . Let

$$X_n = \sum_{k=0}^n V_k, \quad n \in \mathbb{N}$$
(17.1.3)

so that  $X = \{X_n : n \in \mathbb{N}\}$  is simply the *partial sum process* associated with V.

For the partial sum process X,

1. If  $\mathbb{E}(V_n) \geq 0$  for  $n \in \mathbb{N}_+$  then  $oldsymbol{X}$  is a sub-martingale.

2. If  $\mathbb{E}(V_n) \leq 0$  for  $n \in \mathbb{N}_+$  then  $oldsymbol{X}$  is a super-martingale.

3. If  $\mathbb{E}(V_n) = 0$  for  $n \in \mathbb{N}_+$  then  $oldsymbol{X}$  is a martingale.

Proof

Let  $\mathscr{F}_n=\sigma\{X_0,X_1,\ldots,X_n\}=\sigma\{V_0,V_1,\ldots,V_n\}$  for  $n\in\mathbb{N}.$  Note first that

$$\mathbb{E}(|X_n|) \le \sum_{k=0}^n \mathbb{E}(|V_k|) < \infty, \quad n \in \mathbb{N}$$
(17.1.4)

Next,

$$\mathbb{E}\left(X_{n+1} \mid \mathscr{F}_n\right) = \mathbb{E}\left(X_n + V_{n+1} \mid \mathscr{F}_n\right) = \mathbb{E}\left(X_n \mid \mathscr{F}_n\right) + \mathbb{E}\left(V_{n+1} \mid \mathscr{F}_n\right) = X_n + \mathbb{E}(V_{n+1}), \quad n \in \mathbb{N}$$
(17.1.5)

The last equality holds since  $X_n$  is measurable with respect to  $\mathscr{F}_n$  and  $V_{n+1}$  is independent of  $\mathscr{F}_n$ . The results now follow from the definitions.

In terms of gambling, if  $X_0 = V_0$  is the gambler's initial fortune and  $V_i$  is the gambler's net winnings on the *i*th game, then  $X_n$  is the gamblers net fortune after n games for  $n \in \mathbb{N}_+$ . But partial sum processes associated with independent sequences are important far beyond gambling. In fact, much of classical probability deals with partial sums of independent and *identically distributed* variables. The entire chapter on Random Samples explores this setting.

Note that  $\mathbb{E}(X_n) = \sum_{k=0}^n \mathbb{E}(V_k)$ . Hence condition (a) is equivalent to  $n \mapsto \mathbb{E}(X_n)$  increasing, condition (b) is equivalent to  $n \mapsto \mathbb{E}(X_n)$  decreasing, and condition (c) is equivalent to  $n \mapsto \mathbb{E}(X_n)$  constant. Here is another martingale associated with the partial sum process, known as the *second moment martingale*.

Suppose that  $\mathbb{E}(V_k)=0$  for  $k\in\mathbb{N}_+$  and  $\mathrm{var}(V_k)<\infty$  for  $k\in\mathbb{N}.$  Let

$$Y_n = X_n^2 - \operatorname{var}(X_n), \quad n \in \mathbb{N}$$
(17.1.6)

Then  $\boldsymbol{Y} = \{Y_n : n \in \mathbb{N}\}$  is a martingale with respect to  $\boldsymbol{X}$ .

Proof

Again, let  $\mathscr{F}_n = \sigma\{X_0, X_1, \dots, X_n\}$  for  $n \in \mathbb{N}$ . Since the sequence V is independent, note that

$$\operatorname{var}(X_n) = \operatorname{var}\left(\sum_{k=0}^n V_k\right) = \sum_{k=0}^n \operatorname{var}(V_k)$$
(17.1.7)

Also,  $\operatorname{var}(V_k) = \mathbb{E}(V_k^2)$  since  $\mathbb{E}(V_k) = 0$  for  $k \in \mathbb{N}_+$ . In particular,  $\mathbb{E}(|Y_n|) < \infty$  for  $n \in \mathbb{N}$ . Next for  $n \in \mathbb{N}$ ,

$$\begin{split} \mathbb{E}(Y_{n+1} \mid \mathscr{F}_n) &= \mathbb{E}\left[X_{n+1}^2 - \operatorname{var}(X_{n+1}) \mid \mathscr{F}_n\right] = \mathbb{E}\left[(X_n + V_{n+1})^2 - \operatorname{var}(X_{n+1}) \mid \mathscr{F}_n\right] \\ &= \mathbb{E}\left[X_n^2 + 2X_n V_{n+1} + V_{n+1}^2 - \operatorname{var}(X_{n+1}) \mid \mathscr{F}_n\right] = X_n^2 + 2X_n \mathbb{E}(V_{n+1}) + \mathbb{E}(V_{n+1}^2) - \operatorname{var}(X_{n+1}) \end{split}$$

since  $X_n$  is measurable with respect to  $\mathscr{F}_n$  and  $V_{n+1}$  is independent of  $\mathscr{F}_n$ . But  $\mathbb{E}(V_{n+1}) = 0$  and  $E(V_{n+1}^2) - \operatorname{var}(X_{n+1}) = -\operatorname{var}(X_n)$ . Hence we have  $\mathbb{E}(Y_{n+1} \mid \mathscr{F}_n) = X_n^2 - \operatorname{var}(X_n) = Y_n$  for  $n \in \mathbb{N}$ .

So under the assumptions in this theorem, both *X* and *Y* are martingales. We will generalize the results for partial sum processes below in the discussion on processes with independent increments.

#### Martingale Difference Sequences

In the last discussion, we saw that the partial sum process associated with a sequence of independent, mean 0 variables is a martingale. Conversely, every martingale in discrete time can be written as a partial sum process of *uncorrelated* mean 0 variables. This representation gives some significant insight into the theory of martingales generally. Suppose that  $\mathbf{X} = \{X_n : n \in \mathbb{N}\}$  is a martingale with respect to the filtration  $\mathfrak{F} = \{\mathscr{F}_n : n \in \mathbb{N}\}$ .

Let  $V_0 = X_0$  and  $V_n = X_n - X_{n-1}$  for  $n \in \mathbb{N}_+$ . The process  $V = \{V_n : n \in \mathbb{N}\}$  is the martingale difference sequence associated with X and

$$X_n = \sum_{k=0}^n V_k, \quad n \in \mathbb{N}$$
(17.1.8)

As promised, the martingale difference variables have mean 0, and in fact satisfy a stronger property.

Suppose that  $V = \{V_n : n \in \mathbb{N}\}$  is the martingale difference sequence associated with **X**. Then

1. V is adapted to  $\mathfrak{F}$ . 2.  $\mathbb{E}(V_n \mid \mathscr{F}_k) = 0$  for  $k, n \in \mathbb{N}$  with k < n. 3.  $\mathbb{E}(V_n) = 0$  for  $n \in \mathbb{N}_+$ 

Proof

- 1. Of course  $V_0 = X_0$  is measurable with respect to  $\mathscr{F}_0$ . For  $n \in \mathbb{N}_+$ ,  $X_n$  and  $X_{n-1}$ , and hence  $V_n$  are measurable with respect to  $\mathscr{F}_n$
- 2. Let  $k \in \mathbb{N}$  . By the martingale and adapted properties,

$$\mathbb{E}(V_{k+1} \mid \mathscr{F}_k) = \mathbb{E}(X_{k+1} \mid \mathscr{F}_k) - E(X_k \mid \mathscr{F}_k) = X_k - X_k = 0$$
(17.1.9)

Next by the tower property,

$$\mathbb{E}(V_{k+2} \mid \mathscr{F}_k) = \mathbb{E}[\mathbb{E}(V_{k+2} \mid \mathscr{F}_{k+1}) \mid \mathscr{F}_k] = 0$$
(17.1.10)

Continuing (or using induction) gives the general result.

3. Since X is a martingale, it has constant mean, as noted above. Hence  $\mathbb{E}(V_n) = \mathbb{E}(X_n) - \mathbb{E}(X_{n-1}) = 0$  for  $n \in \mathbb{N}_+$ . We could also use part (b).

Also as promised, if the martingale variables have finite variance, then the martingale difference variables are uncorrelated.

Suppose again that  $V = \{V_n : n \in \mathbb{N}\}$  is the martingale difference sequence associated with the martingale X. Assume that  $var(X_n) < \infty$  for  $n \in \mathbb{N}$ . Then V is an uncorrelated sequence. Moreover,

$$\operatorname{var}(X_n) = \sum_{k=0}^n \operatorname{var}(V_k) = \operatorname{var}(X_0) + \sum_{k=1}^n \mathbb{E}(V_k^2), \quad n \in \mathbb{N}$$
 (17.1.11)

Proof

Let  $k, n \in \mathbb{N}$  with k < n. To show that  $V_k$  and  $V_n$  are uncorrelated, we just need to show that  $\mathbb{E}(V_k V_n) = 0$  (since  $E(V_n) = 0$ ). But by the previous result,

$$\mathbb{E}(V_k V_n) = \mathbb{E}[\mathbb{E}(V_k V_n \mid \mathscr{F}_k)] = \mathbb{E}[V_k \mathbb{E}(V_n \mid \mathscr{F}_k)] = 0$$
(17.1.12)

Finally, the variance of a sum of uncorrelated variables is the sum of the variances. Since  $V_k$  has mean 0,  $var(V_k) = \mathbb{E}(V_k^2)$  for  $k \in \mathbb{N}_+$ . Hence the formula for  $var(X_n)$  holds.

We now know that a discrete-time martingale is the partial sum process associated with a sequence of uncorrelated variables. Hence we might hope that there are martingale versions of the fundamental theorems that hold for a partial sum process associated with an independent sequence. This turns out to be true, and is a basic reason for the importance of martingales.

#### Discrete-Time Random Walks

Suppose that  $V = \{V_n : n \in \mathbb{N}\}$  is a sequence of independent random variables with  $\{V_n : n \in \mathbb{N}_+\}$  identically distributed. We assume that  $\mathbb{E}(|V_n|) < \infty$  for  $n \in \mathbb{N}$  and we let a denote the common mean of  $\{V_n : n \in \mathbb{N}_+\}$ . Let  $X = \{X_n : n \in \mathbb{N}\}$  be the partial sum process associated with V so that

$$X_n = \sum_{i=0}^n V_i, \quad n \in \mathbb{N}$$
(17.1.13)

This setting is a special case of the more general partial sum process considered above. The process X is sometimes called a (discretetime) *random walk*. The initial position  $X_0 = V_0$  of the walker can have an arbitrary distribution, but then the *steps* that the walker takes are independent and identically distributed. In terms of gambling,  $X_0 = V_0$  is the initial fortune of the gambler playing a sequence of independent and identical games. If  $V_i$  is the amount won (or lost) on game  $i \in \mathbb{N}_+$ , then  $X_n$  is the gambler's net fortune after n games.

For the random walk  $\boldsymbol{X}$ ,

- 1.  $\boldsymbol{X}$  is a martingale if a = 0.
- 2.  $\boldsymbol{X}$  is a sub-martingale if  $a \geq 0$ .
- 3.  $\boldsymbol{X}$  is a super-martingale if  $a \leq 0$

For the second moment martingale, suppose that  $V_n$  has common mean a = 0 and common variance  $b^2 < \infty$  for  $n \in \mathbb{N}_+$ , and that  $\operatorname{var}(V_0) < \infty$ .

## Let $Y_n = X_n^2 - \operatorname{var}(V_0) - b^2 n$ for $n \in \mathbb{N}$ . Then $\boldsymbol{Y} = \{Y_n : n \in \mathbb{N}\}$ is a martingale with respect to $\boldsymbol{X}$ . Proof

This follows from the corresponding result for a general partial sum process, above, since

$$\operatorname{var}(X_n) = \sum_{k=0}^n \operatorname{var}(V_k) = \operatorname{var}(V_0) + b^2 n, \quad n \in \mathbb{N}$$
 (17.1.14)

We will generalize the results for discrete-time random walks below, in the discussion on processes with stationary, independent increments.

#### **Partial Products**

Our next discussion is similar to the one on partial sum processes above, but with products instead of sums. So suppose that  $V = \{V_n : n \in \mathbb{N}\}$  is an independent sequence of nonnegative random variables with  $\mathbb{E}(V_n) < \infty$  for  $n \in \mathbb{N}$ . Let

$$X_n = \prod_{i=0}^n V_i, \quad n \in \mathbb{N}$$
(17.1.15)

so that  $X = \{X_n : n \in \mathbb{N}\}$  is the *partial product process* associated with X.

For the partial product process X,

1. If  $\mathbb{E}(V_n) = 1$  for  $n \in \mathbb{N}_+$  then  $\boldsymbol{X}$  is a martingale with respect to  $\boldsymbol{V}$ 2. If  $\mathbb{E}(V_n) \ge 1$  for  $n \in \mathbb{N}_+$  then  $\boldsymbol{X}$  is a sub-martingale with respect to  $\boldsymbol{V}$ 3. If  $\mathbb{E}(V_n) \le 1$  for  $n \in \mathbb{N}_+$  then  $\boldsymbol{X}$  is a super-martingale with respect to  $\boldsymbol{V}$ 

Proof

Let  $\mathscr{F}_n=\sigma\{V_0,V_1,\ldots,V_n\}$  for  $n\in\mathbb{N}$  . Since the variables are independent,

$$\mathbb{E}(X_n) = \prod_{i=0}^n \mathbb{E}(V_i) < \infty \tag{17.1.16}$$

Next,

$$\mathbb{E}\left(X_{n+1} \mid \mathscr{F}_n\right) = \mathbb{E}\left(X_n V_{n+1} \mid \mathscr{F}_n\right) = X_n \mathbb{E}(V_{n+1} \mid \mathscr{F}_n) = X_n \mathbb{E}(V_{n+1}) \quad n \in \mathbb{N}$$
(17.1.17)

since  $X_n$  is measurable with respect to  $\mathscr{F}_n$  and  $V_{n+1}$  is independent of  $\mathscr{F}_n$ . The results now follow from the definitions.

As with random walks, a special case of interest is when  $\{V_n : n \in \mathbb{N}_+\}$  is an identically distributed sequence.

#### The Simple Random Walk

Suppose now that that  $V = \{V_n : n \in \mathbb{N}\}$  is a sequence of independent random variables with  $\mathbb{P}(V_i = 1) = p$  and  $\mathbb{P}(V_i = -1) = 1 - p$  for  $i \in \mathbb{N}_+$ , where  $p \in (0, 1)$ . Let  $X = \{X_n : n \in \mathbb{N}\}$  be the partial sum process associated with V so that

$$X_n = \sum_{i=0}^n V_i, \quad n \in \mathbb{N}$$
(17.1.18)

Then X is the simple random walk with parameter p, and of course, is a special case of the more general random walk studied above. In terms of gambling, our gambler plays a sequence of independent and identical games, and on each game, wins  $\notin 1$  with probability p and loses  $\notin 1$  with probability 1 - p. So if  $V_0$  is the gambler's initial fortune, then  $X_n$  is her net fortune after n games.

For the simple random walk,

If p > <sup>1</sup>/<sub>2</sub> then **X** is a sub-martingale.
 If p < <sup>1</sup>/<sub>2</sub> then **X** is a super-martingale.
 If p = <sup>1</sup>/<sub>2</sub> then **X** is a martingale.

Proof

Note that  $\mathbb{E}(V_n) = p - (1-p) = 2p - 1$  for  $n \in \mathbb{N}_+$ , so the results follow from the theorem above.

So case (a) corresponds to favorable games, case (b) to unfavorable games, and case (c) to fair games.

Open the simulation of the simple symmetric random. For various values of the number of trials n, run the simulation 1000 times and note the general behavior of the sample paths.

Here is the second moment martingale for the simple, symmetric random walk.

Consider the simple random walk with parameter  $p = \frac{1}{2}$ , and let  $Y_n = X_n^2 - var(V_0) - n$  for  $n \in \mathbb{N}$ . Then  $\mathbf{Y} = \{Y_n : n \in \mathbb{N}\}$  is a martingale with respect to  $\mathbf{X}$ 

Proof

Note that  $\mathbb{E}(V_i) = 0$  and  $\operatorname{var}(V_i) = 1$  for each  $i \in \mathbb{N}_+$ , so the result follows from the general result above.

But there is another martingale that can be associated with the simple random walk, known as *De Moivre's martingale* and named for one of the early pioneers of probability theory, Abraham De Moivre.

$$Z_n = \left(\frac{1-p}{p}\right)^{X_n} \tag{17.1.19}$$

Then  $\boldsymbol{Z} = \{Z_n : n \in \mathbb{N}\}$  is a martingale with respect to  $\boldsymbol{X}$ .

Proof

Note that

For  $n \in \mathbb{N}$  define

$$Z_n = \prod_{k=0}^n \left(\frac{1-p}{p}\right)^{V_k}, \quad n \in \mathbb{N}$$
(17.1.20)

and

$$\mathbb{E}\left[\left(\frac{1-p}{p}\right)^{V_{k}}\right] = \left(\frac{1-p}{p}\right)^{1} p + \left(\frac{1-p}{p}\right)^{-1} (1-p) = 1, \quad k \in \mathbb{N}_{+}$$
(17.1.21)

So the result follows from the theorem above on partial products.

#### The Beta-Bernoulli Process

Recall that the beta-Bernoulli process is constructed by randomizing the success parameter in a Bernoulli trials process with a beta distribution. Specifically we have a random variable P that has the beta distribution with parameters  $a, b \in (0, \infty)$ , and a sequence of indicator variables  $X = (X_1, X_2, ...)$  such that given  $P = p \in (0, 1)$ , X is a sequence of independent variables with  $\mathbb{P}(X_i = 1) = p$  for  $i \in \mathbb{N}_+$ . As usual, we couch this in reliability terms, so that  $X_i = 1$  means *success* on trial i and  $X_i = 0$  means *failure*. In our study of this process, we showed that the finite-dimensional distributions are given by

$$\mathbb{P}(X_1=x_1,X_2=x_2,\ldots,X_n=x_n)=rac{a^{[k]}b^{[n-k]}}{(a+b)^{[n]}},\quad n\in\mathbb{N}_+,\;(x_1,x_2,\ldots,x_n)\in\{0,1\}^n$$
(17.1.22)

where we use the ascending power notation  $r^{[j]} = r(r+1)\cdots(r+j-1)$  for  $r \in \mathbb{R}$  and  $j \in \mathbb{N}$ . Next, let  $\mathbf{Y} = \{Y_n : n \in \mathbb{N}\}$  denote the partial sum process associated with  $\mathbf{X}$ , so that once again,

$$Y_n = \sum_{i=1}^n X_i, \quad n \in \mathbb{N}$$
(17.1.23)

Of course  $Y_n$  is the number of success in the first *n* trials and has the beta-binomial distribution defined by

$$\mathbb{P}(Y_n = k) = \binom{n}{k} \frac{a^{[k]} b^{[n-k]}}{(a+b)^{[n]}}, \quad k \in \{0, 1, \dots, n\}$$
(17.1.24)

Now let

$$Z_n = \frac{a+Y_n}{a+b+n}, \quad n \in \mathbb{N}$$
(17.1.25)

This variable also arises naturally. Let  $\mathscr{F}_n = \sigma\{X_1, X_2, \dots, X_n\}$  for  $n \in \mathbb{N}$ . Then as shown in the section on the beta-Bernoulli process,  $Z_n = \mathbb{E}(X_{n+1} \mid \mathscr{F}_n) = \mathbb{E}(P \mid \mathscr{F}_n)$ . In statistical terms, the second equation means that  $Z_n$  is the *Bayesian estimator* of the unknown success probability p in a sequence of Bernoulli trials, when p is modeled by the random variable P.

 $\boldsymbol{Z} = \{Z_n : n \in \mathbb{N}\}$  is a martingale with respect to  $\boldsymbol{X}$ .

Proof

Note that  $0 \leq Z_n \leq 1$  so  $\mathbb{E}(Z_n) < \infty$  for  $n \in \mathbb{N}$  . Next,

$$\mathbb{E}\left(Z_{n+1} \mid \mathscr{F}_n\right) = \mathbb{E}\left[\frac{a+Y_{n+1}}{a+b+n+1} \mid \mathscr{F}_n\right] = \frac{\mathbb{E}\left[a+(Y_n+X_{n+1}) \mid \mathscr{F}_n\right]}{a+b+n+1} = \frac{a+Y_n + \mathbb{E}\left(X_{n+1} \mid \mathscr{F}_n\right)}{a+b+n+1} \quad (17.1.26)$$

As noted above,  $\mathbb{E}(X_{n+1} \mid \mathscr{F}_n) = (a+Y_n)/(a+b+n)$ . Substituting into the displayed equation above and doing a bit of algebra we have

$$\mathbb{E}(Z_{n+1} \mid \mathscr{F}_n) = \frac{(a+Y_n) + (a+Y_n)/(a+b+n)}{a+b+n+1} = \frac{a+Y_n}{a+b+n} = Z_n$$
(17.1.27)

Open the beta-Binomial experiment. Run the simulation 1000 times for various values of the parameters, and compare the empirical probability density function with the true probability density function.

#### Pólya's Urn Process

Recall that in the simplest version of Pólya's urn process, we start with an urn containing a red and b green balls. At each discrete time step, we select a ball at random from the urn and then replace the ball and add c new balls of the same color to the urn. For the parameters, we need  $a, b \in \mathbb{N}_+$  and  $c \in \mathbb{N}$ . For  $i \in \mathbb{N}_+$ , let  $X_i$  denote the color of the ball selected on the *i*th draw, where 1 means red and 0 means green. The process  $\mathbf{X} = \{X_n : n \in \mathbb{N}_+\}$  is a classical example of a sequence of exchangeable yet dependent variables. Let  $\mathbf{Y} = \{Y_n : n \in \mathbb{N}\}$  denote the partial sum process associated with  $\mathbf{X}$ , so that once again,

$$Y_n = \sum_{i=1}^n X_i, \quad n \in \mathbb{N}$$
(17.1.28)

Of course  $Y_n$  is the total number of red balls selected in the first n draws. Hence at time  $n \in \mathbb{N}$ , the total number of red balls in the urn is  $a + cY_n$ , while the total number of balls in the urn is a + b + cn and so the *proportion* of red balls in the urn is

$$Z_n = \frac{a + cY_n}{a + b + cn} \tag{17.1.29}$$

 $\boldsymbol{Z} = \{Z_n : n \in \mathbb{N}\}$  is a martingale with respect to  $\boldsymbol{X}$ .

Indirect proof

If c = 0 then  $Z_n = a/(a+b)$  for  $n \in \mathbb{N}$  so Z is a constant martingale. If  $c \in \mathbb{N}_+$  then Z is equivalent to the beta-Bernoulli process with parameters a/c and b/c. Moreover,

$$Z_n = \frac{a+cY_n}{a+b+cn} = \frac{a/c+Y_n}{a/c+b/c+n}, \quad n \in \mathbb{N}$$
(17.1.30)

So *Z* is a martingale by the previous theorem.

Direct Proof

Trivially,  $0 \leq Z_n \leq 1$  so  $\mathbb{E}(Z_n) < \infty$  for  $n \in \mathbb{N}$ . Let  $\mathscr{F}_n = \sigma\{X_1, X_2, \dots, X_n\}$ . For  $n \in \mathbb{N}$ ,

$$\mathbb{E}\left(Z_{n+1} \mid \mathscr{F}_n\right) = \mathbb{E}\left[\frac{a+cY_{n+1}}{a+b+c(n+1)} \mid \mathscr{F}_n\right] = \frac{\mathbb{E}\left[a+c\left(Y_n+X_{n+1}\right) \mid \mathscr{F}_n\right]}{a+b+c(n+1)} = \frac{a+cY_n+c\mathbb{E}\left(X_{n+1} \mid \mathscr{F}_n\right)}{a+b+cn+c} \quad (17.1.31)$$

since  $Y_n$  is measurable with respect to  $\mathscr{F}_n$ . But the probability of selecting a red ball on draw n + 1, given the history of the process up to time n, is simply the proportion of red balls in the urn at time n. That is,

$$\mathbb{E}\left(X_{n+1} \mid \mathscr{F}_n\right) = \mathbb{P}\left(X_{n+1} = 1 \mid \mathscr{F}_n\right) = Z_n = \frac{a + cY_n}{a + b + cn}$$
(17.1.32)

Substituting and simplifying gives  $\mathbb{E}\left(Z_{n+1} \mid \mathscr{F}_n\right) = Z_n$ .

Open the simulation of Pólya's Urn Experiment. Run the simulation 1000 times for various values of the parameters, and compare the empirical probability density function of the number of red ball selected to the true probability density function.

#### Processes with Independent Increments.

Our first example above concerned the partial sum process X associated with a sequence of independent random variables V. Such processes are the only ones in discrete time that have *independent increments*. That is, for  $m, n \in \mathbb{N}$  with  $m \leq n, X_n - X_m$  is independent of  $(X_0, X_1, \ldots, X_m)$ . The random walk process has the additional property of *stationary increments*. That is, the distribution of  $X_n - X_m$  is the same as the distribution of  $X_{n-m} - X_0$  for  $m, n \in \mathbb{N}$  with  $m \leq n$ . Let's consider processes in discrete or continuous time with these properties. Thus, suppose that  $X = \{X_t : t \in T\}$  satisfying the basic assumptions above relative to the filtration  $\mathfrak{F} = \{\mathscr{F}_s : s \in T\}$ . Here are the two definitions.

The process  $oldsymbol{X}$  has

- 1. *Independent increments* if  $X_t X_s$  is independent of  $\mathscr{F}_s$  for all  $s, t \in T$  with s < t.
- 2. *Stationary increments* if  $X_t X_s$  has the same distribution as  $X_{t-s} X_0$  for all  $s, t \in T$ .

Processes with stationary and independent increments were studied in the Chapter on Markov processes. In continuous time (with the continuity assumptions we have imposed), such a process is known as a *Lévy process*, named for Paul Lévy, and also as a *continuous-time random walk*. For a process with independent increments (not necessarily stationary), the connection with martingales depends on the mean function *m* given by  $m(t) = \mathbb{E}(X_t)$  for  $t \in T$ .

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  has independent increments.

1. If m is increasing then X is a sub-martingale.

- 2. If m is decreasing then X is a super-martingale.
- 3. If m is constant then  $\boldsymbol{X}$  is a martingale

Proof

The proof is just like the one above for partial sum processes. Suppose that  $s, t \in [0, \infty)$  with s < t. Then

$$E(X_t \mid \mathscr{F}_s) = \mathbb{E}[X_s + (X_t - X_s) \mid \mathscr{F}_s] = \mathbb{E}(X_s \mid \mathscr{F}_s) + \mathbb{E}(X_t - X_s \mid \mathscr{F}_s)$$
(17.1.33)

But  $X_s$  is measurable with respect to  $\mathscr{F}_s$  and  $X_t - X_s$  is independent of  $\mathscr{F}_s$  So

$$\mathbb{E}\left(X_t \mid \mathscr{F}_s\right) = X_s + \mathbb{E}(X_t - X_s) = X_s + m(t) - m(s) \tag{17.1.34}$$

Compare this theorem with the corresponding theorem for the partial sum process above. Suppose now that  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  is a stochastic process as above, with mean function m, and let  $Y_t = X_t - m(t)$  for  $t \in [0, \infty)$ . The process  $\mathbf{Y} = \{Y_t : t \in [0, \infty)\}$  is sometimes called the *compensated process* associated with  $\mathbf{X}$  and has mean function 0. If  $\mathbf{X}$  has independent increments, then clearly so does  $\mathbf{Y}$ . Hence the following result is a trivial corollary to our previous theorem.

Suppose that X has independent increments. The compensated process Y is a martingale.

Next we give the *second moment martingale* for a process with independent increments, generalizing the second moment martingale for a partial sum process.

Suppose that  $X = \{X_t : t \in T\}$  has independent increments with constant mean function and with  $var(X_t) < \infty$  for  $t \in T$ . Then  $Y = \{Y_t : t \in T\}$  is a martingale where

$$Y_t = X_t^2 - \operatorname{var}(X_t), \quad t \in T$$
 (17.1.35)

Proof

The proof is essentially the same as for the partial sum process in discrete time. Suppose that  $s, t \in T$  with s < t. Note that  $\mathbb{E}(Y_t \mid \mathscr{F}_s) = \mathbb{E}(X_t^2 \mid \mathscr{F}_s) - \operatorname{var}(X_t)$ . Next,

$$X_t^2 = [(X_t - X_s) + X_s]^2 = (X_t - X_s)^2 + 2(X_t - X_s)X_s + X_s^2$$
(17.1.36)

But  $X_t - X_s$  is independent of  $\mathscr{F}_s$ ,  $X_s$  is measurable with respect to  $\mathscr{F}_s$ , and  $E(X_t - X_s) = 0$  so

$$\mathbb{E}(X_t^2 \mid \mathscr{F}_s) = \mathbb{E}[(X_t - X_s)^2] + 2X_s \mathbb{E}(X_t - X_s) + X_s^2 = \mathbb{E}[(X_t - X_s)^2] + X_s^2$$
(17.1.37)

But also by independence and since  $X_t - X_s$  has mean 0,

$$\operatorname{var}(X_t) = \operatorname{var}[(X_t - X_s) + X_s] = \operatorname{var}(X_s) + \operatorname{var}(X_t - X_s)^2 = \operatorname{var}(X_s) + \mathbb{E}[(X_t - X_s)^2$$
(17.1.38)

Putting the pieces together gives

$$\mathbb{E}(Y_t \mid \mathscr{F}_s) = X_s^2 - \operatorname{var}(X_s) = Y_s \tag{17.1.39}$$

Of course, since the mean function is constant, X is also a martingale. For processes with independent *and* stationary increments (that is, random walks), the last two theorems simplify, because the mean and variance functions simplify.

Suppose that  $X = \{X_t : t \in T\}$  has stationary, independent increments, and let  $a = \mathbb{E}(X_1 - X_0)$ . Then

- 1.  $\boldsymbol{X}$  is a martingale if a = 0
- 2.  $\boldsymbol{X}$  is a sub-martingale if  $a \ge 0$
- 3. *X* is a super-martingale if  $a \leq 0$

Proof

Recall that the mean function m is given by  $m(t) = \mathbb{E}(X_0) + at$  for  $t \in T$ , so the result follows from the corresponding result for a process with independent increments.

Compare this result with the corresponding one above for discrete-time random walks. Our next result is the second moment martingale. Compare this with the second moment martingale for discrete-time random walks.

Suppose that  $\mathbf{X} = \{X_t : t \in T\}$  has stationary, independent increments with  $\mathbb{E}(X_0) = \mathbb{E}(X_1)$  and  $b^2 = \mathbb{E}(X_1^2) < \infty$ . Then  $\mathbf{Y} = \{Y_t : t \in T\}$  is a martingale where

$$Y_t = X_t^2 - \operatorname{var}(X_0) - b^2 t, \quad t \in T$$
 (17.1.40)

Proof

(†)

Recall that if  $\mathbb{E}(X_0) = \mathbb{E}(X_1)$  then X has constant mean function. Also,  $var(X_t) = var(X_0) + b^2 t$ , so the result follows from the corresponding result for a process with independent increments.

In discrete time, as we have mentioned several times, all of these results reduce to the earlier results for partial sum processes and random walks. In continuous time, the Poisson processes, named of course for Simeon Poisson, provides examples. The standard (homogeneous) Poisson counting process  $N = \{N_t : t \in [0, \infty)\}$  with constant rate  $r \in (0, \infty)$  has stationary, independent increments and mean function given by m(t) = rt for  $t \in [0, \infty)$ . More generally, suppose that  $r : [0, \infty) \to (0, \infty)$  is piecewise continuous (and non-constant). The non-homogeneous Poisson counting process  $N = \{N_t : t \in [0, \infty)\}$  with rate function r has independent increments and mean function given by

$$m(t) = \int_0^t r(s) \, ds, \quad t \in [0,\infty)$$
 (17.1.41)

The increment  $N_t - N_s$  has the Poisson distribution with parameter m(t) - m(s) for  $s, t \in [0, \infty)$  with s < t, so the process does not have stationary increments. In all cases, m is increasing, so the following results are corollaries of our general results:

Let  $N = \{N_t : t \in [0,\infty)\}$  be the Poisson counting process with rate function  $r : [0,\infty) \to (0,\infty)$ . Then

1. N is a sub-martingale

2. The compensated process  $oldsymbol{X} = \{N_t - m(t) : t \in [0,\infty)\}$  is a martinagle.

Open the simulation of the Poisson counting experiment. For various values of r and t, run the experiment 1000 times and compare the empirical probability density function of the number of arrivals with the true probability density function.

We will see further examples of processes with stationary, independent increments in continuous time (and so also examples of continuoustime martingales) in our study of Brownian motion.

#### Likelihood Ratio Tests

Suppose that  $(S, \mathscr{S}, \mu)$  is a general measure space, and that  $X = \{X_n : n \in \mathbb{N}\}$  is a sequence of independent, identically distributed random variables, taking values in *S*. In statistical terms, *X* corresponds to *sampling* from the common distribution, which is usually not completely known. Indeed, the central problem in statistics is to draw inferences about the distribution from observations of *X*. Suppose now that the underlying distribution either has probability density function  $g_0$  or probability density function  $g_1$ , with respect to  $\mu$ . We assume that  $g_0$  and  $g_1$  are positive on *S*. Of course the common special cases of this setup are

- *S* is a measurable subset of  $\mathbb{R}^n$  for some  $n \in \mathbb{N}_+$  and  $\mu = \lambda_n$  is *n*-dimensional Lebesgue measure on *S*.
- *S* is a countable set and  $\mu = \#$  is counting measure on *S*.

The likelihood ratio test is a hypothesis test, where the null and alternative hypotheses are

- $H_0$ : the probability density function is  $g_0$ .
- *H*<sub>1</sub>: the probability density function is *g*<sub>1</sub>.

The test is based on the test statistic

$$L_n = \prod_{i=1}^n \frac{g_0(X_i)}{g_1(X_i)}, \quad n \in \mathbb{N}$$
(17.1.42)

known as the *likelihood ratio test statistic*. Small values of the test statistic are evidence in favor of the alternative hypothesis  $H_1$ . Here is our result.

Under the alternative hypothesis  $H_1$ , the process  $L = \{L_n : n \in \mathbb{N}\}$  is a martingale with respect to X, known as the *likelihood ratio martingale*.

Proof

Let  $\mathscr{F}_n=\sigma\{X_1,X_2,\ldots,X_n\}.$  For  $n\in\mathbb{N}$  ,

$$\mathbb{E}\left(L_{n+1} \mid \mathscr{F}_n\right) = \mathbb{E}\left[L_n \frac{g_0(X_{n+1})}{g_1(X_{n+1})} \mid \mathscr{F}_n\right] = L_n \mathbb{E}\left[\frac{g_0(X_{n+1})}{g_1(X_{n+1})}\right]$$
(17.1.43)

Since  $L_n$  is measurable with respect to  $\mathscr{F}_n$  and  $g_0(X_{n+1})/g_1(X_{n+1})$  is independent of  $\mathscr{F}_n$ . But under  $H_1$ , and using the change of variables formula for expected value, we have

$$\mathbb{E}\left[\frac{g_0(X_{n+1})}{g_1(X_{n+1})}\right] = \int_S \frac{g_0(x)}{g_1(x)} g_1(x) \, d\mu(x) = \int_S g_0(x) \, d\mu(x) = 1 \tag{17.1.44}$$

This result also follows essentially from the theorem above on partial products. The sequence  $\mathbf{Z} = (Z_1, Z_2, ...)$  given by  $Z_i = g_0(X_i)/g_1(X_i)$  for  $i \in \mathbb{N}_+$  is independent and identically distributed, and as just shown, has mean 1 under  $H_1$ .

#### **Branching Processes**

In the simplest model of a *branching process*, we have a system of *particles* each of which can die out or split into new particles of the same type. The fundamental assumption is that the particles act independently, each with the same offspring distribution on  $\mathbb{N}$ . We will let f denote the (discrete) probability density function of the number of offspring of a particle, m the mean of the distribution, and  $\phi$  the probability generating function of the distribution. Thus, if U is the number of children of a particle, then  $f(n) = \mathbb{P}(U = n)$  for  $n \in \mathbb{N}$ ,  $m = \mathbb{E}(U)$ , and  $\phi(t) = \mathbb{E}(t^U)$  defined at least for  $t \in (-1, 1]$ .

Our interest is in *generational time* rather than *absolute time*: the original particles are in generation 0, and recursively, the children a particle in generation n belong to generation n+1. Thus, the stochastic process of interest is  $\mathbf{X} = \{X_n : n \in \mathbb{N}\}$  where  $X_n$  is the

number of particles in the *n*th generation for  $n \in \mathbb{N}$ . The process X is a Markov chain and was studied in the section on discrete-time branching chains. In particular, one of the fundamental problems is to compute the probability q of extinction starting with a single particle:

$$q = \mathbb{P}(X_n = 0 \text{ for some } n \in \mathbb{N} \mid X_0 = 1)$$

$$(17.1.45)$$

Then, since the particles act independently, the probability of extinction starting with  $x \in \mathbb{N}$  particles is simply  $q^x$ . We will assume that f(0) > 0 and f(0) + f(1) < 1. This is the interesting case, since it means that a particle has a positive probability of dying without children and a positive probability of producing more than 1 child. The fundamental result, you may recall, is that q is the smallest fixed point of  $\phi$  (so that  $\phi(q) = q$ ) in the interval [0, 1]. Here are two martingales associated with the branching process:

Each of the following is a martingale with respect to X.

1. 
$$oldsymbol{Y}=\{Y_n:n\in\mathbb{N}\}$$
 where  $Y_n=X_n/m^n$  for  $n\in\mathbb{N}.$ 

2. 
$$\mathbf{Z} = \{Z_n : n \in \mathbb{N}\}$$
 where  $Z_n = q^{X_n}$  for  $n \in \mathbb{N}$ .

Proof

Let  $\mathscr{F}_n=\sigma\{X_0,X_1,\ldots,X_n\}.$  For  $n\in\mathbb{N}$  , note that  $X_{n+1}$  can be written in the form

$$X_{n+1} = \sum_{i=1}^{X_n} U_i \tag{17.1.46}$$

where  $U = (U_1, U_2, ...)$  is a sequence of independent variables, each with PDF f (and hence mean  $\mu$  and PGF  $\phi$ ), and with U independent of  $\mathscr{P}_n$ . Think of  $U_i$  as the number of children of the *i*th particle in generation n.

1. For  $n \in \mathbb{N}$  ,

$$\mathbb{E}(Y_{n+1} \mid \mathscr{F}_n) = \mathbb{E}\left(\frac{X_{n+1}}{m^{n+1}} \mid \mathscr{F}_n\right) = \frac{1}{m^{n+1}} \mathbb{E}\left(\sum_{i=0}^{X_n} U_i \mid \mathscr{F}_n\right) = \frac{1}{m^{n+1}} m X_n = \frac{X_n}{m^n} = Y_n$$
(17.1.47)

2. For  $n \in \mathbb{N}$ 

$$\mathbb{E}\left(Z_{n+1} \mid \mathscr{F}_n\right) = \mathbb{E}\left(q^{X_{n+1}} \mid \mathscr{F}_n\right) = \mathbb{E}\left(q^{\sum_{i=1}^{X_n} U_i} \mid \mathscr{F}_n\right) = \left[\phi(q)\right]^{X_n} = q^{X_n} = Z_n$$
(17.1.48)

#### **Doob's Martingale**

Our next example is one of the simplest, but most important. Indeed, as we will see later in the section on convergence, this type of martingale is almost universal in the sense that every uniformly integrable martingale is of this type. The process is constructed by conditioning a fixed random variable on the  $\sigma$ -algebras in a given filtration, and thus *accumulating information* about the random variable.

Suppose that  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$  is a filtration on the probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ , and that X is a real-valued random variable with  $\mathbb{E}(|X|) < \infty$ . Define  $X_t = \mathbb{E}(X | \mathscr{F}_t)$  for  $t \in T$ . Then  $X = \{X_t : t \in T\}$  is a martingale with respect to  $\mathfrak{F}$ .

#### Proof

For  $t \in T$ , recall that  $|X_t| = |\mathbb{E}(X | \mathscr{F}_t)| \le \mathbb{E}(|X| | \mathscr{F}_t)$ . Taking expected values gives  $\mathbb{E}(|X_t|) \le \mathbb{E}(|X|) < \infty$ . Suppose that  $s, t \in T$  with s < t. Using the tower property of conditional expected value,

$$\mathbb{E}\left(X_{t} \mid \mathscr{F}_{s}\right) = \mathbb{E}\left[\mathbb{E}\left(X \mid \mathscr{F}_{t}\right) \mid \mathscr{F}_{s}\right] = \mathbb{E}\left(X \mid \mathscr{F}_{s}\right) = X_{s}$$
(17.1.49)

The martingale in the last theorem is known as *Doob's martingale* and is named for Joseph Doob who did much of the pioneering work on martingales. It's also known as the *Lévy martingale*, named for Paul Lévy.

Doob's martingale arises naturally in the statistical context of Bayesian estimation. Suppose that  $\mathbf{X} = (X_1, X_2, ...)$  is a sequence of independent random variables whose common distribution depends on an unknown real-valued parameter  $\theta$ , with values in a parameter space  $A \subseteq \mathbb{R}$ . For each  $n \in \mathbb{N}_+$ , let  $\mathscr{P}_n = \sigma\{X_1, X_2, ..., X_n\}$  so that  $\mathfrak{F} = \{\mathscr{P}_n : n \in \mathbb{N}_+\}$  is the natural filtration associated with  $\mathbf{X}$ . In Bayesian estimation, we model the unknown parameter  $\theta$  with a random variable  $\Theta$  taking values in A and having a specified *prior distribution*. The *Bayesian estimator* of  $\theta$  based on the sample  $\mathbf{X}_n = (X_1, X_2, ..., X_n)$  is

$$U_n = \mathbb{E}(\Theta \mid \mathscr{F}_n), \quad n \in \mathbb{N}_+$$
 (17.1.50)

So it follows that the sequence of Bayesian estimators  $U = (U_n : n \in \mathbb{N}_+)$  is a Doob martingale. The estimation referred to in the discussion of the beta-Bernoulli process above is a special case.

#### **Density Functions**

For this example, you may need to review general measures and density functions in the chapter on Distributions. We start with our probability space  $(\Omega, \mathscr{F}, \mathbb{P})$  and filtration  $\mathfrak{F} = \{\mathscr{F}_n : n \in \mathbb{N}\}$  in discrete time. Suppose now that  $\mu$  is a finite measure on the sample space  $(\Omega, \mathscr{F})$ . For each  $n \in \mathbb{N}$ , the restriction of  $\mu$  to  $\mathscr{F}_n$  is a measure on the measurable space  $(\Omega, \mathscr{F}_n)$ , and similarly the restriction of  $\mathbb{P}$  to  $\mathscr{F}_n$  is a probability measure on  $(\Omega, \mathscr{F}_n)$ . To save notation and terminology, we will refer to these as  $\mu$  and  $\mathbb{P}$  on  $\mathscr{F}_n$ , respectively. Suppose now that  $\mu$  is absolutely continuous with respect to  $\mathbb{P}$  on  $\mathscr{F}_n$  for each  $n \in \mathbb{N}$ . Recall that this means that if  $A \in \mathscr{F}_n$  and  $\mathbb{P}(A) = 0$  then  $\mu(B) = 0$  for every  $B \in \mathscr{F}_n$  with  $B \subseteq A$ . By the Radon-Nikodym theorem,  $\mu$  has a density function  $X_n : \Omega \to \mathbb{R}$  with respect to  $\mathbb{P}$  on  $\mathscr{F}_n$  for each  $n \in \mathbb{N}_+$ . The density function of a measure with respect to a positive measure is known as a *Radon-Nikodym derivative*. The theorem and the derivative are named for Johann Radon and Otto Nikodym. Here is our main result.

 $oldsymbol{X} = \{X_n : n \in \mathbb{N}\}$  is a martingale with respect to  $\mathfrak{F}$ .

Proof

Let  $n \in \mathbb{N}$ . By definition,  $X_n$  is measurable with respect to  $\mathscr{F}_n$ . Also,  $\mathbb{E}(|X_n|) = \|\mu\|$  (the total variation of  $\mu$ ) for each  $n \in \mathbb{N}$ . Since  $\mu$  is a finite measure,  $\|\mu\| < \infty$ . By definition,

$$\mu(A) = \int_{A} X_n d\mathbb{P} = \mathbb{E}(X_n; A), \quad A \in \mathscr{F}_n$$
(17.1.51)

On the other hand, if  $A \in \mathscr{F}_n$  then  $A \in \mathscr{F}_{n+1}$  and so  $\mu(A) = \mathbb{E}(X_{n+1}; A)$ . So to summarize,  $X_n$  is  $\mathscr{F}_n$ -measurable and  $\mathbb{E}(X_{n+1}; A) = \mathbb{E}(X_n; A)$  for all  $A \in \mathscr{F}_n$ . By definition, this means that  $\mathbb{E}(X_{n+1} \mid \mathscr{F}_n) = X_n$ , and so X is a martingale with respect to  $\mathfrak{F}$ .

Note that  $\mu$  may not be absolutely continuous with respect to  $\mathbb{P}$  on  $\mathscr{F}$  or even on  $\mathscr{F}_{\infty} = \sigma (\bigcup_{n=0}^{\infty} \mathscr{F}_n)$ . On the other hand, if  $\mu$  *is* absolutely continuous with respect to  $\mathbb{P}$  on  $\mathscr{F}_{\infty}$  then  $\mu$  has a density function X with respect to  $\mathbb{P}$  on  $\mathscr{F}_{\infty}$ . So a natural question in this case is the relationship between the martingale X and the random variable X. You may have already guessed the answer, but at any rate it will be given in the section on convergence.

## 17.2: Properties and Constructions

## Basic Theory

### Preliminaries

As in the Introduction, we start with a stochastic process  $X = \{X_t : t \in T\}$  on an underlying probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ , having state space  $\mathbb{R}$ , and where the index set T (representing time) is either  $\mathbb{N}$  (discrete time) or  $[0, \infty)$  (continuous time). Next, we have a filtration  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$ , and we assume that X is *adapted* to  $\mathfrak{F}$ . So  $\mathfrak{F}$  is an increasing family of sub  $\sigma$ -algebras of  $\mathscr{F}$  and  $X_t$ is measurable with respect to  $\mathscr{F}_t$  for  $t \in T$ . We think of  $\mathscr{F}_t$  as the collection of events up to time  $t \in T$ . We assume that  $\mathbb{E}(|X_t|) < \infty$ , so that the mean of  $X_t$  exists as a real number, for each  $t \in T$ . Finally, in continuous time where  $T = [0, \infty)$ , we make the standard assumptions that X is right continuous and has left limits, and that the filtration  $\mathfrak{F}$  is right continuous and complete. Please recall the following from the Introduction:

#### Definitions

- 1. *X* is a *martingale* with respect to  $\mathfrak{F}$  if  $\mathbb{E}(X_t \mid \mathscr{F}_s) = X_s$  for all  $s, t \in T$  with  $s \leq t$ .
- 2. **X** is a *sub-martingale* with respect to  $\mathfrak{F}$  if  $\mathbb{E}(X_t \mid \mathscr{F}_s) \geq X_s$  for all  $s, t \in T$  with  $s \leq t$ .
- 3. **X** is a *super-martingale* with respect to  $\mathfrak{F}$  if  $\mathbb{E}(X_t \mid \mathscr{F}_s) \leq X_s$  for all  $s, t \in T$  with  $s \leq t$ .

Our goal in this section is to give a number of basic properties of martingales and to give ways of constructing martingales from other types of processes. The deeper, fundamental theorems will be studied in the following sections.

#### **Basic Properties**

Our first result is that the martingale property is preserved under a coarser filtration.

Suppose that the process X and the filtration  $\mathfrak{F}$  satisfy the basic assumptions above and that  $\mathfrak{G}$  is a filtration coarser than  $\mathfrak{F}$  so that  $\mathscr{G}_t \subseteq \mathscr{F}_t$  for  $t \in T$ . If X is a martingale (sub-martingale, super-martingale) with respect to  $\mathfrak{F}$  and X is adapted to  $\mathfrak{G}$  then X is a martingale (sub-martingale) with respect to  $\mathfrak{G}$ .

Proof

Suppose that  $s, t \in T$  with  $s \le t$ . The proof uses the tower and increasing properties of conditional expected value, and the fact that X is adapted to  $\mathfrak{G}$ 

1. If  $\boldsymbol{X}$  is a martingale with respect to  $\mathfrak{F}$  then

$$\mathbb{E}(X_t \mid \mathscr{G}_s) = \mathbb{E}\left[\mathbb{E}(X_t \mid \mathscr{F}_s) \mid \mathscr{G}_s\right] = \mathbb{E}(X_s \mid \mathscr{G}_s) = X_s \tag{17.2.1}$$

2. If  $\boldsymbol{X}$  is a sub-martinagle with respect to  $\mathfrak{F}$  then

$$\mathbb{E}(X_t \mid \mathscr{G}_s) = \mathbb{E}\left[\mathbb{E}(X_t \mid \mathscr{F}_s) \mid \mathscr{G}_s\right] \ge \mathbb{E}(X_s \mid \mathscr{G}_s) = X_s \tag{17.2.2}$$

3. If  $\boldsymbol{X}$  is a super-martinagle with respect to  $\mathfrak{F}$  then

$$\mathbb{E}(X_t \mid \mathscr{G}_s) = \mathbb{E}\left[\mathbb{E}(X_t \mid \mathscr{F}_s) \mid \mathscr{G}_s\right] \le \mathbb{E}(X_s \mid \mathscr{G}_s) = X_s \tag{17.2.3}$$

In particular, if X is a martingale (sub-martingale, super-martingale) with respect to *some* filtration, then it is a martingale (sub-martingale, super-martingale) with respect to its own natural filtration.

The relations that define martingales, sub-martingales, and super-martingales hold for the ordinary (unconditional) expected values. We had this result in the last section, but it's worth repeating.

Suppose that  $s, t \in T$  with  $s \leq t$  .

- 1. If **X** is a martingale with respect to  $\mathfrak{F}$  then  $\mathbb{E}(X_s) = \mathbb{E}(X_t)$ .
- 2. If **X** is a sub-martingale with respect to  $\mathfrak{F}$  then  $\mathbb{E}(X_s) \leq \mathbb{E}(X_t)$ .
- 3. If **X** is a super-martingale with respect to  $\mathfrak{F}$  then  $\mathbb{E}(X_s) \ge \mathbb{E}(X_t)$ .

Proof

The results follow directly from the definitions, and the critical fact that  $\mathbb{E}\left[\mathbb{E}\left(X_t \mid \mathscr{F}_s\right)\right] = \mathbb{E}(X_t)$  for  $s, t \in T$ .

So if X is a martingale then X has constant expected value, and this value is referred to as the *mean* of X. The martingale properties are preserved under sums of the stochastic processes.

For the processes  $X = \{X_t : t \in T\}$  and  $Y = \{Y_t : t \in T\}$ , let  $X + Y = \{X_t + Y_t : t \in T\}$ . If X and Y are martingales (sub-martingales, super-martinagles) with respect to  $\mathfrak{F}$  then X + Y is a martingale (sub-martingale, super-martinagle) with respect to  $\mathfrak{F}$ .

Proof

The results follow easily from basic properties of expected value and conditional expected value. First note that  $\mathbb{E}(|X_t + Y_t|) \le \mathbb{E}(|X_t|) + \mathbb{E}(|Y_t|) < \infty$  for  $t \in T$ . Next  $\mathbb{E}(X_t + Y_t \mid \mathscr{F}_s) = \mathbb{E}(X_t \mid \mathscr{F}_s) + \mathbb{E}(Y_t \mid \mathscr{F}_s)$  for  $s, t \in T$  with  $s \le t$ .

The sub-martingale and super-martingale properties are preserved under multiplication by a positive constant and are reversed under multiplication by a negative constant.

For the process  $X = \{X_t : t \in T\}$  and the constant  $c \in \mathbb{R}$ , let  $cX = \{cX_t : t \in T\}$ .

- 1. If  $\boldsymbol{X}$  is a martingale with respect to  $\mathfrak{F}$  then  $c\boldsymbol{X}$  is also a martingale with respect to  $\mathfrak{F}$
- 2. If *X* is a sub-martingale with respect to  $\mathfrak{F}$ , then *cX* is a sub-martingale if c > 0, a super-martingale if c < 0, and a martingale if c = 0.
- 3. If *X* is a super-martingale with respect to  $\mathfrak{F}$ , then *cX* is a super-martingale if c > 0, a sub-martingale if c < 0, and a martingale if c = 0.

Proof

The results follow easily from basic properties of expected value and conditional expected value. First note that  $\mathbb{E}(|cX_t|) = |c|\mathbb{E}(|X_t|) < \infty$  for  $t \in T$ . Next  $\mathbb{E}(cX_t \mid \mathscr{F}_s) = c\mathbb{E}(X_t \mid \mathscr{F}_s)$  for  $s, t \in T$  with  $s \leq t$ .

Property (a), together with the previous additive property, means that the collection of martingales with respect to a fixed filtration  $\Im$  forms a vector space. Here is a class of transformations that turns martingales into sub-martingales.

Suppose that X takes values in an interval  $S \subseteq \mathbb{R}$  and that  $g: S \to \mathbb{R}$  is convex with  $\mathbb{E}[|g(X_t)|] < \infty$  for  $t \in T$ . If either of the following conditions holds then  $g(X) = \{g(X_t) : t \in T\}$  is a sub-martingale with respect to  $\mathfrak{F}$ :

- 1. **X** is a martingale.
- 2.  $\boldsymbol{X}$  is a sub-martingale and g is also increasing.

Proof

Here is the most important special case of the previous result:

Suppose again that  $\boldsymbol{X}$  is a martingale with respect to  $\mathfrak{F}$ . Let  $k \in [1, \infty)$  and suppose that  $\mathbb{E}\left(|X_t|^k\right) < \infty$  for  $t \in T$ . Then the process  $|\boldsymbol{X}|^k = \left\{|X_t|^k : t \in T\right\}$  is a sub-martingale with respect to  $\mathfrak{F}$ Proof

Figure 17.2.2: The graphs of  $x\mapsto |x|$  ,  $x\mapsto |x|^2$  and  $x\mapsto |x|^3$  on the interval [-2,2]

In particular, if X is a martingale relative to  $\mathfrak{F}$  then  $|X| = \{|X_t| : t \in T\}$  is a sub-martingale relative to  $\mathfrak{F}$ . Here is a related result that we will need later. First recall that the *positive and negative parts* of  $x \in \mathbb{R}$  are  $x^+ = \max\{x, 0\}$  and  $x^- = \max\{-x, 0\}$ , so that  $x^+ \ge 0$ ,  $x^- \ge 0$ ,  $x = x^+ - x^-$ , and  $|x| = x^+ + x^-$ .

Figure 17.2.3: The graph of  $x\mapsto x^+$  on the interval [-5,5]

If  $X = \{X_t : t \in T\}$  is a sub-martingale relative to  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$  then  $X^+ = \{X_t^+ : t \in T\}$  is also a sub-martingale relative to  $\mathfrak{F}$ .

Proof

As shown in the graph above, the function  $x \mapsto x^+$  is increasing and convex on  $\mathbb{R}$ .

Our last result of this discussion is that if we sample a continuous-time martingale at an increasing sequence of time points, we get a discrete-time martingale.

Suppose again that the process  $X = \{X_t : t \in [0, \infty)\}$  and the filtration  $\mathfrak{F} = \{\mathscr{F}_t : t \in [0, \infty)\}$  satisfy the basic assumptions above. Suppose also that  $\{t_n : n \in \mathbb{N}\} \subset [0, \infty)$  is a strictly increasing sequence of time points with  $t_0 = 0$ , and define  $Y_n = X_{t_n}$  and  $\mathscr{G}_n = \mathscr{F}_{t_n}$  for  $n \in \mathbb{N}$ . If X is a martingale (sub-martingale, super-martingale) with respect to  $\mathfrak{F}$  then  $Y = \{Y_n : n \in \mathbb{N}\}$  is a martingale (sub-martingale, super-martingale) with respect to  $\mathfrak{G}$ .

#### Proof

Since the time points are increasing, it's clear that  $\mathfrak{G}$  is a discrete-time filtration. Next,  $\mathbb{E}(|Y_n|) = \mathbb{E}(|X_{t_n}|) < \infty$ . Finally, suppose that X is a martingale and  $n, k \in \mathbb{N}$  with k < n. Then  $t_k < t_n$  so

$$\mathbb{E}(Y_n \mid \mathscr{G}_k) = \mathbb{E}\left(X_{t_n} \mid \mathscr{F}_{t_k}\right) = X_{t_k} = Y_k \tag{17.2.4}$$

Hence Y is also a martingale. The proofs for sub and super-martingales are similar, but with inequalities replacing the second equality.

This result is often useful for extending proofs of theorems in discrete time to continuous time.

#### The Martingale Transform

Our next discussion, in discrete time, shows how to build a new martingale from an existing martingale and an predictable process. This construction turns out to be very useful, and has an interesting gambling interpretation. To review the definition, recall that  $\{Y_n : n \in \mathbb{N}_+\}$  is *predictable* relative to the filtration  $\mathfrak{F} = \{\mathscr{P}_n : n \in \mathbb{N}\}$  if  $Y_n$  is measurable with respect to  $\mathscr{P}_{n-1}$  for  $n \in \mathbb{N}_+$ . Think of  $Y_n$  as the bet that a gambler makes on game  $n \in \mathbb{N}_+$ . The gambler can base the bet on all of the information she has at that point, including the outcomes of the previous n-1 games. That is, she can base the bet on the information encoded in  $\mathscr{P}_{n-1}$ .

Suppose that  $X = \{X_n : n \in \mathbb{N}\}$  is adapted to the filtration  $\mathfrak{F} = \{\mathscr{F}_n : n \in \mathbb{N}\}$  and that  $Y = \{Y_n : n \in \mathbb{N}_+\}$  is predictable relative to  $\mathfrak{F}$ . The *transform* of X by Y is the process  $Y \cdot X$  defined by

$$(\boldsymbol{Y} \cdot \boldsymbol{X})_n = X_0 + \sum_{k=1}^n Y_k (X_k - X_{k-1}), \quad n \in \mathbb{N}$$
 (17.2.5)

The motivating example behind the transform, in terms of a gambler making a sequence of bets, is given in an example below. Note that  $\mathbf{Y} \cdot \mathbf{X}$  is also adapted to  $\mathfrak{F}$ . Note also that the transform depends on  $\mathbf{X}$  only through  $X_0$  and  $\{X_n - X_{n-1} : n \in \mathbb{N}_+\}$ . If  $\mathbf{X}$  is a martingale, this sequence is the martingale difference sequence studied Introduction.

Suppose  $X = \{X_n : n \in \mathbb{N}\}$  is adapted to the filtration  $\mathfrak{F} = \{\mathscr{F}_n : n \in \mathbb{N}\}$  and that  $Y = \{Y_n : n \in \mathbb{N}\}$  is a bounded process, predictable relative to  $\mathfrak{F}$ .

1. If **X** is a martingale relative to  $\mathfrak{F}$  then **Y** · **X** is also a martingale relative to  $\mathfrak{F}$ .

2. If X is a sub-martingle relative to  $\mathfrak{F}$  and Y is nonnegative, then  $Y \cdot X$  is also a sub-martingale relative to  $\mathfrak{F}$ .

3. If **X** is a super-martingle relative to  $\mathfrak{F}$  and **Y** is nonnegative, then  $Y \cdot X$  is also a super-martingale relative to  $\mathfrak{F}$ .

Proof

Suppose that  $|Y_n| \leq c$  for  $n \in \mathbb{N}$  where  $c \in (0, \infty)$ . Then

$$\mathbb{E}(|(\boldsymbol{Y} \cdot \boldsymbol{X})_n|) \leq \mathbb{E}(|X_0|) + c \sum_{k=1}^n [\mathbb{E}(|X_k|) + \mathbb{E}(|X_{k-1}|)] < \infty, \quad n \in \mathbb{N}$$
(17.2.6)

Next, for  $n \in \mathbb{N}$  ,

$$\begin{split} \mathbb{E}\left[ (\boldsymbol{Y} \cdot \boldsymbol{X})_{n+1} \mid \mathscr{F}_n \right] &= \mathbb{E}\left[ (\boldsymbol{Y} \cdot \boldsymbol{X})_n + Y_{n+1}(X_{n+1} - X_n) \mid \mathscr{F}_n \right] = (\boldsymbol{Y} \cdot \boldsymbol{X})_n + Y_{n+1} \mathbb{E}\left( X_{n+1} - X_n \mid \mathscr{F}_n \right) \\ &= (\boldsymbol{Y} \cdot \boldsymbol{X})_n + Y_{n+1} [\mathbb{E}(X_{n+1} \mid \mathscr{F}_n) - X_n] \end{split}$$

since  $(\mathbf{Y} \cdot \mathbf{X})_n$ ,  $Y_{n+1}$  and  $X_n$  are  $\mathscr{F}_n$ -measurable. The results now follow from the definitions of martingle, sub-martingale, and super-martingale.

This construction is known as a *martingale transform*, and is a discrete version of the stochastic integral that we will study in the chapter on Brownian motion. The result also holds if instead of Y being bounded, we have X bounded and  $\mathbb{E}(|Y_n|) < \infty$  for  $n \in \mathbb{N}_+$ 

#### The Doob Decomposition

The next result, in discrete time, shows how to decompose a basic stochastic process into a martingale and a predictable process. The result is known as the *Doob decomposition theorem* and is named for Joseph Doob who developed much of the modern theory of martingales.

Suppose that  $X = \{X_n : n \in \mathbb{N}\}$  satisfies the basic assumptions above relative to the filtration  $\mathfrak{F} = \{\mathscr{F}_n : n \in \mathbb{N}\}$ . Then  $X_n = Y_n + Z_n$  for  $n \in \mathbb{N}$  where  $Y = \{Y_n : n \in \mathbb{N}\}$  is a martingale relative to  $\mathfrak{F}$  and  $Z = \{Z_n : n \in \mathbb{N}\}$  is predictable relative to  $\mathfrak{F}$ . The decomposition is unique.

1. If  $\boldsymbol{X}$  is a sub-martingale relative to  $\mathfrak{F}$  then  $\boldsymbol{Z}$  is increasing.

2. If  $\boldsymbol{X}$  is a super-martingale relative to  $\mathfrak{F}$  then  $\boldsymbol{Z}$  is decreasing.

Proof

Recall that the basic assumptions mean that  $X = \{X_n : n \in \mathbb{N}\}$  is adapted to  $\mathfrak{F}$  and  $\mathbb{E}(|X_n|) < \infty$  for  $n \in \mathbb{N}$ . Define  $Z_0 = 0$  and

$$Z_n = \sum_{k=1}^n \left[ \mathbb{E}(X_k \mid \mathscr{F}_{k-1}) - X_{k-1} 
ight], \quad n \in \mathbb{N}_+$$
 (17.2.7)

Then  $Z_n$  is measurable with respect to  $\mathscr{F}_{n-1}$  for  $n \in \mathbb{N}_+$  so Z is predictable with respect to  $\mathfrak{F}$ . Now define

$$Y_n = X_n - Z_n = X_n - \sum_{k=1}^n \left[ \mathbb{E}(X_k \mid \mathscr{F}_{k-1}) - X_{k-1} \right], \quad n \in \mathbb{N}$$
(17.2.8)

Then  $\mathbb{E}(|Y_n|) < \infty$  and trivially  $X_n = Y_n + Z_n~~ ext{for}~n \in \mathbb{N}$  . Next,

$$egin{aligned} \mathbb{E}(Y_{n+1} \mid \mathscr{F}_n) &= \mathbb{E}(X_{n+1} \mid \mathscr{F}_n) - Z_{n+1} = \mathbb{E}(X_{n+1} \mid \mathscr{F}_n) - \sum_{k=1}^{n+1} \left[ \mathbb{E}(X_k \mid \mathscr{F}_{k-1}) - X_{k-1} 
ight] \ &= X_n - \sum_{k=1}^n \left[ \mathbb{E}(X_k \mid \mathscr{F}_{k-1}) - X_{k-1} 
ight] = Y_n, \quad n \in \mathbb{N} \end{aligned}$$

Hence Y is a martingale. Conversely, suppose that X has the decomposition in terms of Y and Z given in the theorem. Since Y is a martingale and Z is predictable,

$$\begin{split} \mathbb{E}(X_n - X_{n-1} \mid \mathscr{F}_{n-1}) &= \mathbb{E}(Y_n \mid \mathscr{F}_{n-1}) - \mathbb{E}(Y_{n-1} \mid \mathscr{F}_{n-1}) + \mathbb{E}(Z_n \mid \mathscr{F}_{n-1}) - \mathbb{E}(Z_{n-1} \mid \mathscr{F}_{n-1}) \\ &= Y_{n-1} - Y_{n-1} + Z_n - Z_{n-1} = Z_n - Z_{n-1}, \quad n \in \mathbb{N}_+ \end{split}$$

Also  $Z_0 = 0$  so X uniquely determines Z. But  $Y_n = X_n - Z_n$  for  $n \in \mathbb{N}$ , so X uniquely determines Y also.

1. If X is a sub-martingale then  $\mathbb{E}(X_n \mid \mathscr{F}_{n-1}) - X_{n-1} \ge 0$  for  $n \in \mathbb{N}_+$  so Z is increasing.

2. If X is a super-martingale then  $\mathbb{E}(X_n \mid \mathscr{F}_{n-1}) - X_{n-1} \leq 0$  for  $n \in \mathbb{N}_+$  so Z is decreasing.

A decomposition of this form is more complicated in continuous time, in part because the definition of a predictable process is more subtle and complex. The decomposition theorem holds in continuous time, with our basic assumptions and the additional assumption that the collection of random variables { $X_{\tau} : \tau$  is a finite-valued stopping time} is uniformly integrable. The result is known as the *Doob-Meyer decomposition theorem*, named additionally for Paul Meyer.

#### **Markov Processes**

As you might guess, there are important connections between Markov processes and martingales. Suppose that  $X = \{X_t : t \in T\}$  is a (homogeneous) Markov process with state space  $(S, \mathscr{S})$ , relative to the filtration  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$ . Let  $P = \{P_t : t \in T\}$  denote the collection of transition kernesl of X, so that

$$P_t(x,A) = \mathbb{P}(X_t \in A \mid X_0 = x), \quad x \in S, A \in \mathscr{S}$$

$$(17.2.9)$$

Recall that (like all probability kernels),  $P_t$  operates (on the right) on (measurable) functions  $h: S \to \mathbb{R}$  by the rule

$$P_t h(x) = \int_S P_t(x, dy) h(y) = \mathbb{E}[h(X_t) \mid X_0 = x], \quad x \in S$$
 (17.2.10)

assuming as usual that the expected value exists. Here is the critical definition that we will need.

Suppose that  $h: S \to \mathbb{R}$  and that  $\mathbb{E}[|h(X_t)|] < \infty$  for  $t \in T$ .

1. *h* is *harmonic* for  $\boldsymbol{X}$  if  $P_t h = h$  for  $t \in T$ .

2. *h* is sub-harmonic for  $\boldsymbol{X}$  if  $P_t h \ge h$  for  $t \in T$ .

3. *h* is *super-harmonic* for  $\boldsymbol{X}$  if  $P_t h \leq h$  for  $t \in T$ .

The following theorem gives the fundamental connection between the two types of stochastic processes. Given the similarity in the terminology, the result may not be a surprise.

Suppose that  $h: S \to \mathbb{R}$  and  $\mathbb{E}[|h(X_t)|] < \infty$  for  $t \in T$ . Define  $h(\mathbf{X}) = \{h(X_t) : t \in T\}$ .

- 1. *h* is harmonic for **X** if and only if  $h(\mathbf{X})$  is a martingale with respect to  $\mathfrak{F}$ .
- 2. *h* is sub-harmonic for **X** if and only if  $h(\mathbf{X})$  is a sub-martingale with respect to  $\mathfrak{F}$ .
- 3. *h* is super-harmonic for **X** if and only if  $h(\mathbf{X})$  is a super-martingale with respect to  $\mathfrak{F}$ .

Proof

Suppose that  $s, t \in T$  with  $s \leq t$ . Then by the Markov property,

$$\mathbb{E}[h(X_t) \mid \mathscr{F}_s] = \mathbb{E}[h(X_t) \mid X_s] = P_{t-s}h(X_s)$$
(17.2.11)

So if h is harmonic,  $\mathbb{E}[h(X_t) | \mathscr{F}_s] = h(X_s)$  so  $\{h(X_t) : t \in T\}$  is a martingale. Conversely, if  $\{h(X_t) : t \in T\}$  is a martingale, then  $P_{t-s}h(X_s) = h(X_s)$ . Letting s = 0 and  $X_0 = x$  gives  $P_th(x) = h(x)$  so h is harmonic. The proofs for sub and super-martingales are similar, with inequalities replacing the equalities.

Several of the examples given in the Introduction can be re-interpreted in the context of harmonic functions of Markov chains. We explore some of these below.

## Examples

Let  $\mathscr{R}$  denote the usual set of Borel measurable subsets of  $\mathbb{R}$ , and for  $A \in \mathscr{R}$  and  $x \in \mathbb{R}$  let  $A - x = \{y - x : y \in A\}$ . Let I denote the identity function on  $\mathbb{R}$ , so that I(x) = x for  $x \in \mathbb{R}$ . We will need this notation in a couple of our applications below.

#### **Random Walks**

Suppose that  $V = \{V_n : n \in \mathbb{N}\}$  is a sequence of independent, real-valued random variables, with  $\{V_n : n \in \mathbb{N}_+\}$  identically distributed and having common probability measure Q on  $(\mathbb{R}, \mathscr{R})$  and mean  $a \in \mathbb{R}$ . Recall from the Introduction that the partial sum process  $X = \{X_n : n \in \mathbb{N}\}$  associated with V is given by

$$X_n = \sum_{i=0}^n V_i, \quad n \in \mathbb{N}$$
 (17.2.12)

and that X is a (discrete-time) *random walk*. But X is also a discrete-time Markov process with one-step transition kernel P given by P(x, A) = Q(A - x) for  $x \in \mathbb{R}$  and  $A \in \mathscr{R}$ .

The identity function I is

1. Harmonic for  $\boldsymbol{X}$  if a = 0.

2. Sub-harmonic for  $\boldsymbol{X}$  if  $a \ge 0$ .

3. Super-harmonic for  $\boldsymbol{X}$  if  $a \leq 0$ .

Proof

Note that

$$PI(x) = \mathbb{E}(X_1 \mid X_0 = x) = x + \mathbb{E}(X_1 - X_0 \mid X_0 = x) = x + \mathbb{E}(V_1 \mid X_0 = x) = I(x) + a$$
(17.2.13)

Since  $V_1$  and  $X_0 = V_0$  are independent. The results now follow from the definitions.

It now follows from our theorem above that X is a martingale if a = 0, a sub-martingale if a > 0, and a super-martingale if a < 0. We showed these results directly from the definitions in the Introduction.

#### The Simple Random Walk

Suppose now that that  $V = \{V_n : n \in \mathbb{N}\}$  is a sequence of independent random variables with  $\mathbb{P}(V_i = 1) = p$  and  $\mathbb{P}(V_i = -1) = 1 - p$  for  $i \in \mathbb{N}_+$ , where  $p \in (0, 1)$ . Let  $X = \{X_n : n \in \mathbb{N}\}$  be the partial sum process associated with V so that

$$X_n = \sum_{i=0}^n V_i, \quad n \in \mathbb{N}$$
 (17.2.14)

Then X is the simple random walk with parameter p. In terms of gambling, our gambler plays a sequence of independent and identical games, and on each game, wins  $\in 1$  with probability p and loses  $\in 1$  with probability 1 - p. So if  $X_0$  is the gambler's initial fortune, then  $X_n$  is her net fortune after n games. In the Introduction we showed that X is a martingale if  $p = \frac{1}{2}$ , a supermartingale if  $p < \frac{1}{2}$ , and a sub-martingale if  $p > \frac{1}{2}$ . But suppose now that instead of making constant unit bets, the gambler makes bets that depend on the outcomes of previous games. This leads to a martingale transform as studied above.

Suppose that the gambler bets  $Y_n$  on game  $n \in \mathbb{N}_+$  (at even stakes), where  $Y_n \in [0, \infty)$  depends on  $(V_0, V_1, V_2, \dots, V_{n-1})$  and satisfies  $\mathbb{E}(Y_n) < \infty$ . So the process  $\mathbf{Y} = \{Y_n : n \in \mathbb{N}_+\}$  is predictable with respect to  $\mathbf{X}$ , and the gambler's net winnings after n games is

$$(\boldsymbol{Y} \cdot \boldsymbol{X})_n = V_0 + \sum_{k=1}^n Y_k V_k = X_0 + \sum_{k=1}^n Y_k (X_k - X_{k-1})$$
(17.2.15)

1.  $\boldsymbol{Y} \cdot \boldsymbol{X}$  is a sub-martingale if  $p > \frac{1}{2}$ . 2.  $\boldsymbol{Y} \cdot \boldsymbol{X}$  is a super-martingale if  $p < \frac{1}{2}$ .

3.  $\boldsymbol{Y} \cdot \boldsymbol{X}$  is a martingale if  $p = \frac{1}{2}$ .

Proof

Proof

These result follow immediately the theorem for martingale transforms above.

The simple random walk  $m{X}$  is also a discrete-time Markov chain on  $\mathbb Z$  with one-step transition matrix P given by P(x, x+1) = p, P(x, x-1) = 1-p.

The function h given by  $h(x) = \left( rac{1-p}{p} 
ight)^x$  for  $x \in \mathbb{Z}$  is harmonic for  $oldsymbol{X}$ . For  $x \in \mathbb{Z}$ ,  $Ph(x) = ph(x+1) + (1-p)h(x-1) = pigg(rac{1-p}{p}igg)^{x+1} + (1-p)igg(rac{1-p}{p}igg)^{x-1}$  $rac{(1-p)^{x+1}}{p^x} + rac{(1-p)^x}{n^{x-1}} = \left(rac{1-p}{n}
ight)^x [(1-p)+p] = h(x)$ 

It now follows from our theorem above that the process  $Z = \{Z_n : n \in \mathbb{N}\}$  given by  $Z_n = \left(\frac{1-p}{p}\right)^{X_n}$  for  $n \in \mathbb{N}$  is a martingale. We showed this directly from the definition in the Introduction. As you may recall, this is De Moivre's martingale and named for Abraham De Moivre.

#### Branching Processes

Recall the discussion of the simple branching process from the Introduction. The fundamental assumption is that the particles act independently, each with the same offspring distribution on  $\mathbb{N}$ . As before, we will let f denote the (discrete) probability density function of the number of offspring of a particle, m the mean of the distribution, and  $\phi$  the probability generating function of the distribution. We assume that f(0) > 0 and f(0) + f(1) < 1 so that a particle has a positive probability of dying without children and a positive probability of producing more than 1 child. Recall that q denotes the probability of extinction, starting with a single particle.

The stochastic process of interest is  $X = \{X_n : n \in \mathbb{N}\}$  where  $X_n$  is the number of particles in the *n*th generation for  $n \in \mathbb{N}$ . Recall that X is a discrete-time Markov chain on  $\mathbb N$  with one-step transition matrix P given by  $P(x,y)=f^{*x}(y)$  for  $x,\,y\in\mathbb N$ where  $f^{*x}$  denotes the convolution power of order x of f.

The function *h* given by  $h(x) = q^x$  for  $x \in \mathbb{N}$  is harmonic for **X**. Proof For  $x \in \mathbb{N}$ ,  $Ph(x)=\sum_{y\in\mathbb{N}}P(x,y)h(y)=\sum_{y\in\mathbb{N}}f^{*x}(y)q^{y}$ (17.2.16)

The last expression is the probability generating function of  $f^{*x}$  evaluated at q. But this PGF is simply  $\phi^x$  and q is a fixed point of  $\phi$  so we have

$$Ph(x) = [\phi(q)]^{x} = q^{x} = h(x)$$
(17.2.17)

It now follows from our theorem above that the process  $m{Z}=\{Z_n:n\in\mathbb{N}\}$  is a martingale where  $Z_n=q^{X_n}$  for  $n\in\mathbb{N}.$  We showed this directly from the definition in the Introduction. We also showed that the process  $m{Y}=\{Y_n:n\in\mathbb{N}\}$  is a martingale where  $Y_n = X_n/m^n$  for  $n \in \mathbb{N}$ . But we can't write  $Y_n = h(X_n)$  for a function h defined on the state space, so we can't interpret this martingale in terms of a harmonic function.

#### General Random Walks

Suppose that  $X = \{X_t : t \in T\}$  is a stochastic process satisfying the basic assumptions above relative to the filtration  $\mathfrak{F}=\{\mathscr{F}_t:t\in T\}$  . Recall from the Introduction that the term *increment* refers to a difference of the form  $X_{s+t}-X_s$  for  $s,\,t\in T$  .

The process X has independent increments if this increment is always independent of  $\mathscr{F}_s$ , and has stationary increments this increment always has the same distribution as  $X_t - X_0$ . In discrete time, a process with stationary, independent increments is simply a random walk as discussed above. In continuous time, a process with stationary, independent increments (and with the continuity assumptions we have imposed) is called a *continuous-time random walk*, and also a *Lévy process*, named for Paul Lévy.

So suppose that X has stationary, independent increments. For  $t \in T$  let  $Q_t$  denote the probability distribution of  $X_t - X_0$  on  $(\mathbb{R}, \mathscr{R})$ , so that  $Q_t$  is also the probability distribution and  $X_{s+t} - X_s$  for every  $s, t \in T$ . From our previous study, we know that X is a Markov processes with transition kernel  $P_t$  at time  $t \in T$  given by

$$P_t(x,A) = Q_t(A-x); \quad x \in \mathbb{R}, A \in \mathscr{R}$$
 (17.2.18)

We also know that  $\mathbb{E}(X_t - X_0) = at$  for  $t \in T$  where  $a = \mathbb{E}(X_1 - X_0)$  (assuming of course that the last expected value exists in  $\mathbb{R}$ ).

The identity function I is .

- 1. Harmonic for  $\boldsymbol{X}$  if a = 0.
- 2. Sub-harmonic for  $\boldsymbol{X}$  if  $a \ge 0$ .
- 3. Super-harmonic for  $\boldsymbol{X}$  if  $a \leq 0$ .

Proof

Note that

$$P_t I(x) = \mathbb{E}(X_t \mid X_0 = x) = x + \mathbb{E}(X_t - X_0 \mid X_0 = x) = I(x) + at$$
(17.2.19)

since  $X_t - X_0$  is independent of  $X_0$ . The results now follow from the definitions.

It now follows that X is a martingale if a = 0, a sub-martingale if  $a \ge 0$ , and a super-martingale if  $a \le 0$ . We showed this directly in the Introduction. Recall that in continuous time, the Poisson counting process has stationary, independent increments, as does standard Brownian motion

## 17.3: Stopping Times

## **Basic Theory**

As in the Introduction, we start with a stochastic process  $X = \{X_t : t \in T\}$  on an underlying probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ , having state space  $\mathbb{R}$ , and where the index set T (representing time) is either  $\mathbb{N}$  (discrete time) or  $[0, \infty)$  (continuous time). Next, we have a filtration  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$ , and we assume that X is *adapted* to  $\mathfrak{F}$ . So  $\mathfrak{F}$  is an increasing family of sub  $\sigma$ -algebras of  $\mathscr{F}$  and  $X_t$ is measurable with respect to  $\mathscr{F}_t$  for  $t \in T$ . We think of  $\mathscr{F}_t$  as the collection of events up to time  $t \in T$ . We assume that  $\mathbb{E}(|X_t|) < \infty$ , so that the mean of  $X_t$  exists as a real number, for each  $t \in T$ . Finally, in continuous time where  $T = [0, \infty)$ , we make the standard assumption that X is right continuous and has left limits, and that the filtration  $\mathfrak{F}$  is right continuous and complete.

Our general goal in this section is to see if some of the important martingale properties are preserved if the deterministic time  $t \in T$  is replaced by a (random) stopping time. Recall that a random time  $\tau$  with values in  $T \cup \{\infty\}$  is a *stopping time* relative to  $\mathfrak{F}$  if  $\{\tau \leq t\} \in \mathscr{F}_t$  for  $t \in T$ . So a stopping time is a random time that does not require that we see into the future. That is, we can tell if  $\tau \leq t$  from the information available at time t. Next recall that the  $\sigma$ -algebra associated with the stopping time  $\tau$  is

$$\mathscr{F}_{\tau} = \{A \in \mathscr{F} : A \cap \{\tau \le t\} \in \mathscr{F}_t \text{ for all } t \in T\}$$

$$(17.3.1)$$

So  $\mathscr{F}_{\tau}$  is the collection of events up to the random time  $\tau$  just as  $\mathscr{F}_t$  is the collection of events up to the deterministic time  $t \in T$ . In terms of a gambler playing a sequence of games, the time that the gambler decides to stop playing must be a stopping time, and in fact this interpretation is the origin of the name. That is, the time when the gambler decides to stop playing can only depend on the information that the gambler has up to that point in time.

#### **Optional Stopping**

The basic martingale equation  $\mathbb{E}(X_t | \mathscr{F}_s) = X_s$  for  $s, t \in T$  with  $s \leq t$  can be generalized by replacing both s and t by bounded stopping times. The result is known as the *Doob's optional stopping theorem* and is named again for Joseph Doob. Suppose that  $X = \{X_t : t \in T\}$  satisfies the basic assumptions above with respect to the filtration  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$ 

Suppose that are bounded stopping times relative to  $\mathfrak{F}$  with  $\rho \leq \tau$ .

- 1. If **X** is a martingale relative to  $\mathfrak{F}$  then  $\mathbb{E}(X_{\tau} \mid \mathscr{F}_{\rho}) = X_{\rho}$ .
- 2. If **X** is a sub-martingale relative to  $\mathfrak{F}$  then  $\mathbb{E}(X_{\tau} \mid \mathscr{F}_{\rho}) \geq X_{\rho}$ .
- 3. If **X** is a super-martingale relative to  $\mathfrak{F}$  then  $\mathbb{E}(X_{\tau} \mid \mathscr{F}_{\rho}) \leq X_{\rho}$ .

Proof in discrete time

1. Suppose that  $\tau \leq k$  where  $k \in \mathbb{N}_+$  and let  $A \in \mathscr{F}_{\tau}$ . For  $j \in \mathbb{N}$  with  $j \leq k$ ,  $A \cap \{\tau = j\} \in \mathscr{F}_j$ . Hence by the martingale property,

$$\mathbb{E}(X_k; A \cap \{\tau = j\}) = \mathbb{E}(X_j; A \cap \{\tau = j\}) = \mathbb{E}(X_\tau; A \cap \{\tau = j\})$$
(17.3.2)

Since *k* is an upper bound on  $\tau$ , the events  $A \cap \{\tau = j\}$  for  $j = 0, 1, \ldots, k$  partition *A*, so summing the displayed equation over *j* gives  $\mathbb{E}(X_k; A) = \mathbb{E}(X_{\tau}; A)$ . By definition of conditional expectation,  $\mathbb{E}(X_k \mid \mathscr{F}_{\tau}) = X_{\tau}$ . But since *k* is also an upper bound for  $\rho$  we also have  $\mathbb{E}(X_k \mid \mathscr{F}_{\rho}) = X_{\rho}$ . Finally using the tower property we have

$$X_{\rho} = \mathbb{E}(X_k \mid \mathscr{F}_{\rho}) = \mathbb{E}[\mathbb{E}(X_k \mid \mathscr{F}_{\rho}) \mid \mathscr{F}_{\tau}] = \mathbb{E}[\mathbb{E}(X_k \mid \mathscr{F}_{\tau}) \mid \mathscr{F}_{\rho}] = \mathbb{E}(X_{\tau} \mid \mathscr{F}_{\rho})$$
(17.3.3)

2. If X is a sub-martingale, then by the Doob decomposition theorem,  $X_n = Y_n + Z_n$  for  $n \in \mathbb{N}$  where  $Y = \{Y_n : n \in \mathbb{N}\}$  is a martingale relative to  $\mathfrak{F}$  and  $Z = \{Z_n : n \in \mathbb{N}\}$  is increasing and is predictable relative to  $\mathfrak{F}$ . So

$$\mathbb{E}(X_{\tau} \mid \mathscr{F}_{\rho}) = \mathbb{E}(Y_{\tau} \mid \mathscr{F}_{\rho}) + \mathbb{E}(Z_{\tau} \mid \mathscr{F}_{\rho})$$
(17.3.4)

But  $\mathbb{E}(Y_{\tau} \mid \mathscr{F}_{\rho}) = Y_{\rho}$  by part (a) and since  $\mathbf{Z}$  is increasing,  $\mathbb{E}(Z_{\tau} \mid \mathscr{F}_{\rho}) \ge \mathbb{E}(Z_{\rho} \mid \mathscr{F}_{\rho}) = Z_{\rho}$ . Hence  $\mathbb{E}(X_{\tau} \mid \mathscr{F}_{\rho}) \ge X_{\rho}$ . 3. The proof when  $\mathbf{X}$  is a super-martingale is just like (b), except that the process  $\mathbf{Z}$  is decreasing.

Proof in continuous time

Suppose that X is a martingale. We need to show that  $\mathbb{E}(X_{\tau}; A) = \mathbb{E}(X_{\rho}; A)$  for every  $A \in \mathscr{F}_{\rho}$ . Let  $\rho_n = \lceil 2^n \rho \rceil / 2^n$  and  $\tau_n = \lceil 2^n \tau \rceil / 2^n$  for  $n \in \mathbb{N}$ . The stopping times  $\rho_n$  and  $\tau_n$  take values in a countable set  $T_n$  for each  $n \in \mathbb{N}$ , and  $\rho_n \downarrow \rho$  and

 $au_n \downarrow au$  as  $n \to \infty$ . The process  $\{X_t : t \in T_n\}$  is a discrete-time martingale for each  $n \in \mathbb{N}$ . By the right continuity of X,

$$X_{
ho_n} o X_{
ho}, \ X_{ au_n} o X_{ au} ext{ as } n o \infty$$
 (17.3.5)

Suppose next that  $\tau \leq c$  where  $c \in (0, \infty)$  so that  $\rho \leq c$  also. Then  $\rho_n \leq c+1$  and  $\tau_n \leq c+1$  for  $n \in \mathbb{N}$  so the discrete stopping times are uniformly bounded. From the discrete version of the theorem,  $X_{\rho_n} = \mathbb{E} \left( X_{c+1} \mid \mathscr{F}_{\rho_n} \right)$  and  $X_{\tau_n} = \mathbb{E} \left( X_{c+1} \mid \mathscr{F}_{\tau_n} \right)$  for  $n \in \mathbb{N}$ . It then follows that the sequences  $\{ X_{\rho_n} : n \in \mathbb{N} \}$  and  $\{ X_{\tau_n} : n \in \mathbb{N} \}$  are uniformly integrable and hence  $X_{\rho_n} \to X_{\rho}$  and  $X_{\tau_n} \to X_{\tau}$  as  $n \to \infty$  in mean as well as with probability 1. Now let  $A \in \mathscr{F}_{\rho}$ . Since  $\rho \leq \rho_n$ ,  $\mathscr{F}_{\rho} \subseteq \mathscr{F}_{\rho_n}$  and so  $A \in \mathscr{F}_{\rho_n}$  for each  $n \in \mathbb{N}$ . By the theorem in discrete time,

$$\mathbb{E}\left(X_{\tau_n};A\right) = \mathbb{E}\left(X_{\rho_n}:A\right), \quad n \in \mathbb{N}$$
(17.3.6)

Letting  $n \to \infty$  gives  $\mathbb{E}(X_{\tau}; A) = \mathbb{E}(X_{\rho}; A)$ . The proofs in parts (b) and (c) are as in the discrete time.

The assumption that the stopping times are bounded is critical. A <u>counterexample</u> when this assumption does not hold is given below. Here are a couple of simple corollaries:

Suppose again that  $\rho$  and  $\tau$  are bounded stopping times relative to  $\mathfrak{F}$  with  $\rho \leq \tau$ .

1. If **X** is a martingale relative to  $\mathfrak{F}$  then  $\mathbb{E}(X_{\tau}) = \mathbb{E}(X_{\rho})$ .

2. If **X** is a sub-martingale relative to  $\mathfrak{F}$  then  $\mathbb{E}(X_{\tau}) \geq \mathbb{E}(X_{\rho})$ .

3. If **X** is a super-martingale relative to  $\mathfrak{F}$  then  $\mathbb{E}(X_{\tau}) \leq \mathbb{E}(X_{\rho})$ .

Proof

Recall that  $\mathbb{E}(X_{\tau}) = \mathbb{E}[\mathbb{E}(X_{\tau} \mid \mathscr{F}_{\rho})]$ , so the results are immediate from the optional stopping theorem.

Suppose that  $\tau$  is a bounded stopping time relative to  $\mathfrak{F}$ .

- 1. If **X** is a martingale relative to  $\mathfrak{F}$  then  $\mathbb{E}(X_{\tau}) = \mathbb{E}(X_0)$ .
- 2. If **X** is a sub-martingale relative to  $\mathfrak{F}$  then  $\mathbb{E}(X_{\tau}) \geq \mathbb{E}(X_0)$ .
- 3. If **X** is a super-martingale relative to  $\mathfrak{F}$  then  $\mathbb{E}(X_{\tau}) \leq \mathbb{E}(X_0)$ .

#### The Stopped Martingale

For our next discussion, we first need to recall how to stop a stochastic process at a stopping time.

Suppose that X satisfies the assumptions above and that  $\tau$  is a stopping time relative to the filtration  $\mathfrak{F}$ . The *stopped process*  $X^{\tau} = \{X_t^{\tau} : t \in [0, \infty)\}$  is defined by

$$X_t^{\tau} = X_{t \wedge \tau}, \quad t \in [0, \infty) \tag{17.3.7}$$

Details

In continuous time, our standard assumptions ensure that  $X^{\tau}$  is a valid stochastic process and is adapted to  $\mathfrak{F}$ . That is,  $X_t^{\tau}$  is measurable with respect to  $\mathscr{F}_t$  for each  $t \in [0, \infty)$ . Moreover,  $X^{\tau}$  is also right continuous and has left limits.

So  $X_t^{\tau} = X_t$  if  $t < \tau$  and  $X_t^{\tau} = X_{\tau}$  if  $t \ge \tau$ . In particular, note that  $X_0^{\tau} = X_0$ . If  $X_t$  is the fortune of a gambler at time  $t \in T$ , then  $X_t^{\tau}$  is the revised fortune at time t when  $\tau$  is the stopping time of the gamber. Our next result, known as the *elementary stopping theorem*, is that a martingale stopped at a stopping time is still a martingale.

Suppose again that X satisfies the assumptions above, and that  $\tau$  is a stopping time relative to  $\mathfrak{F}$ .

1. If **X** is a martingale relative to  $\mathfrak{F}$  then so is  $X^{\tau}$ .

2. If X is a sub-martingale relative to  $\mathfrak{F}$  then so is  $X^{\tau}$ .

3. If *X* is a super-martingale relative to  $\mathfrak{F}$  then so is *X*<sup>au</sup>.

General proof

If  $s, t \in T$  with  $s \leq t$  then  $\tau \wedge s$  and  $\tau \wedge t$  are bounded stopping times with  $\tau \wedge s \leq \tau \wedge t$ . So the results follows immediately from the optional stopping theorem above.

Special proof in discrete time

In discrete time, there is a simple direct proof using the martingale transform. So suppose that  $T = \mathbb{N}$  and define the process  $Y = \{Y_n : n \in \mathbb{N}_+\}$  by

$$Y_n = \mathbf{1}( au \ge n) = 1 - \mathbf{1}( au \le n - 1), \quad n \in \mathbb{N}_+$$
 (17.3.8)

By definition of a stopping time,  $\{\tau \le n-1\} \in \mathscr{F}_{n-1}$  for  $n \in \mathbb{N}_+$ , so the process  $\boldsymbol{Y}$  is predictable. Of course,  $\boldsymbol{Y}$  is a bounded, nonnegative process also. The transform of  $\boldsymbol{X}$  by  $\boldsymbol{Y}$  is

$$(\boldsymbol{Y}\cdot\boldsymbol{X})_n = X_0 + \sum_{k=1}^n Y_k(X_k - X_{k-1}) = X_0 + \sum_{k=1}^n \mathbf{1}(\tau \ge k)(X_k - X_{k-1}), \quad n \in \mathbb{N}_+$$
 (17.3.9)

But note that  $X_k^{\tau} - X_{k-1}^{\tau} = X_k - X_{k-1}$  if  $\tau \ge k$  and  $X_k^{\tau} - X_{k-1}^{\tau} = X_{\tau} - X_{\tau} = 0$  if  $\tau < k$ . That is,  $X_k^{\tau} - X_{k-1}^{\tau} = \mathbf{1}(\tau \ge k)(X_k - X_{k-1})$ . Hence

$$(m{Y}\cdotm{X})_n = X_0 + \sum_{k=1}^n (X_k^ au - X_{k-1}^ au) = X_0 + X_n^ au - X_0^ au = X_n^ au, \quad n \in \mathbb{N}_+$$
 (17.3.10)

But if X is a martingale (sub-martingale) (super-martingale), then so is the transform  $Y \cdot X = X_{\tau}$ .

The elementary stopping theorem is bad news for the gambler playing a sequence of games. If the games are fair or unfavorable, then no stopping time, regardless of how cleverly designed, can help the gambler. Since a stopped martingale is still a martingale, the the mean property holds.

Suppose again that X satisfies the assumptions above, and that  $\tau$  is a stopping time relative to  $\mathfrak{F}$ . Let  $t \in T$ .

- 1. If **X** is a martingale relative to  $\mathfrak{F}$  then  $\mathbb{E}(X_{t \wedge \tau}) = E(X_0)$
- 2. If  $\boldsymbol{X}$  is a sub-martingale relative to  $\mathfrak{F}$  then  $\mathbb{E}(X_{t \wedge \tau}) \geq E(X_0)$
- 3. If  $\boldsymbol{X}$  is a super-martingale relative to  $\mathfrak{F}$  then  $\mathbb{E}(X_{t \wedge \tau}) \leq E(X_0)$

#### Optional Stopping in Discrete Time

A simple corollary of the optional stopping theorem is that if X is a martingale and  $\tau$  a bounded stopping time, then  $\mathbb{E}(X_{\tau}) = \mathbb{E}(X_0)$  (with the appropriate inequalities if X is a sub-martingale or a super-martingale). Our next discussion centers on other conditions which give these results in discrete time. Suppose that  $X = \{X_n : n \in \mathbb{N}\}$  satisfies the basic assumptions above with respect to the filtration  $\mathfrak{F} = \{\mathscr{P}_n : n \in \mathbb{N}\}$ , and that  $\tau$  is a stopping time relative to  $\mathfrak{F}$ .

Suppose that  $|X_n|$  is bounded uniformly in  $n \in \mathbb{N}$  and that au is finite.

4. If  $oldsymbol{X}$  is a martingale then  $\mathbb{E}(X_{ au}) = \mathbb{E}(X_0)$ .

- 5. If  $oldsymbol{X}$  is a sub-martingale then  $\mathbb{E}(X_{ au}) \geq \mathbb{E}(X_0)$  .
- 6. If  $\boldsymbol{X}$  is a super-martingale then  $\mathbb{E}(X_{\tau}) \leq \mathbb{E}(X_0)$ .

Proof

Assume that X is a super-martingale. The proof for a sub-martingale are similar, and then the results follow immediately for a martingale. The main tool is the mean property above for the stopped super-martingale:

$$\mathbb{E}(X_{\tau \wedge n}) \leq \mathbb{E}(X_0), \quad n \in \mathbb{N}$$
 (17.3.11)

Since  $\tau < \infty$  with probability 1,  $\tau \wedge n \to \tau$  as  $n \to \infty$ , also with probability 1. Since  $|X_n|$  is bounded in  $n \in T$ , it follows from the bounded convergence theorem that  $\mathbb{E}(X_{\tau \wedge n}) \to \mathbb{E}(X_{\tau})$  as  $n \to \infty$ . Letting  $n \to \infty$  in the displayed equation gives  $\mathbb{E}(X_{\tau}) \leq \mathbb{E}(X_0)$ .

Suppose that  $|X_{n+1} - X_n|$  is bounded uniformly in  $n \in \mathbb{N}$  and that  $\mathbb{E}(\tau) < \infty$ .

4. If **X** is a martingale then  $\mathbb{E}(X_{\tau}) = \mathbb{E}(X_0)$ .

5. If  $\boldsymbol{X}$  is a sub-martingale then  $\mathbb{E}(X_{\tau}) \geq \mathbb{E}(X_0)$ .

6. If  $oldsymbol{X}$  is a super-martingale then  $\mathbb{E}(X_{ au}) \leq \mathbb{E}(X_0)$  .

Proof

Assume that X is a super-martingale. The proofs for a sub-martingale are similar, and then the results follow immediately for a martingale. The main tool once again is the mean property above for the stopped super-martingale:

$$\mathbb{E}(X_{ au\wedge n}) \leq \mathbb{E}(X_0), \quad n \in \mathbb{N}$$
 (17.3.12)

Suppose that  $|X_{n+1}-X_n| \leq c \;$  where  $c \in (0,\infty).$  Then

$$|X_{ au\wedge n} - X_0| = \left|\sum_{k=1}^{ au\wedge n} (X_k - X_{k-1})\right| \le \sum_{k=1}^{ au\wedge n} |X_k - X_{k-1}| \le c( au\wedge n) \le c au \tag{17.3.13}$$

Hence  $|X_{\tau \wedge n}| \leq c\tau + |X_0|$ . Since  $\mathbb{E}(\tau) < \infty$  we know that  $\tau < \infty$  with probability 1, so as before,  $\tau \wedge n \to \tau$  as  $n \to \infty$ . Also  $\mathbb{E}(c\tau + |X_0|) < \infty$  so by the dominated convergence theorem,  $\mathbb{E}(X_{\tau \wedge n}) \to \mathbb{E}(X_{\tau})$  as  $n \to \infty$ . So again letting  $n \to \infty$  in the displayed equation gives  $\mathbb{E}(X_{\tau}) \leq \mathbb{E}(X_0)$ .

Let's return to our original interpretation of a martingale X representing the fortune of a gambler playing fair games. The gambler could choose to quit at a random time  $\tau$ , but  $\tau$  would have to be a stopping time, based on the gambler's information encoded in the filtration  $\mathfrak{F}$ . Under the conditions of the theorem, no such scheme can help the gambler in terms of expected value.

#### Examples and Applications

#### The Simple Random Walk

Suppose that  $V = (V_1, V_2, ...)$  is a sequence if independent, identically distributed random variables with  $\mathbb{P}(V_i = 1) = p$  and  $\mathbb{P}(V_i = -1) = 1 - p$  for  $i \in \mathbb{N}_+$ , where  $p \in (0, 1)$ . Let  $X = (X_0, X_1, X_2, ...)$  be the partial sum process associated with V so that

$$X_n = \sum_{i=1}^n V_i, \quad n \in \mathbb{N}$$
 (17.3.14)

Then X is the simple random walk with parameter p. In terms of gambling, our gambler plays a sequence of independent and identical games, and on each game, wins  $\in 1$  with probability p and loses  $\in 1$  with probability 1 - p. So  $X_n$  is the the gambler's total net winnings after n games. We showed in the Introduction that X is a martingale if  $p = \frac{1}{2}$  (the fair case), a sub-martingale if  $p > \frac{1}{2}$  (the favorable case), and a super-martingale if  $p < \frac{1}{2}$  (the unfair case). Now, for  $c \in \mathbb{Z}$ , let

$$\tau_c = \inf\{n \in \mathbb{N} : X_n = c\} \tag{17.3.15}$$

where as usual,  $\inf(\emptyset) = \infty$ . So  $\tau_c$  is the first time that the gambler's fortune reaches *c*. What if the gambler simply continues playing until her net winnings is some specified positive number (say  $\in 1000000$ )? Is that a workable strategy?

Suppose that  $p = \frac{1}{2}$  and that  $c \in \mathbb{N}_+$ . 1.  $\mathbb{P}(\tau_c < \infty) = 1$ 2.  $\mathbb{E}(X_{\tau_c}) = c \neq 0 = \mathbb{E}(X_0)$ 3.  $\mathbb{E}(\tau_c) = \infty$ Proof Parts (a) and (c) hold since **X** is a null re-

Parts (a) and (c) hold since X is a null recurrent Markov chain. Part (b) follows from (a) since trivially  $X_{\tau_c} = c$  if  $\tau_c < \infty$ .

Note that part (b) does not contradict the optional stopping theorem because of part (c). The strategy of waiting until the net winnings reaches a specified goal *c* is unsustainable. Suppose now that the gambler plays until the net winnings either falls to a specified negative number (a loss that she can tolerate) or reaches a specified positive number (a goal she hopes to reach).

```
Suppose again that p = \frac{1}{2}. For a, b \in \mathbb{N}_+, let \tau = \tau_{-a} \wedge \tau_b. Then

1. \mathbb{E}(\tau) < \infty

2. \mathbb{E}(X_{\tau}) = 0

3. \mathbb{P}(\tau_{-a} < \tau_b) = b/(a+b)

Proof
```

1. We will let  $X_0$  have an arbitrary value in the set  $\{-a, -a+1, \dots, b-1, b\}$ , so that we can use Markov chain techniques. Let  $m(x) = \mathbb{E}(\tau \mid X_0 = x)$  for x in this set. Conditioning on the first state and using the Markov property we have

$$m(x) = 1 + \frac{1}{2}m(x-1) + \frac{1}{2}m(x+1), \quad x \in \{-a+1, \dots, b-1\}$$
 (17.3.16)

with boundary conditions m(-a) = m(b) = 0. The linear recurrence relation can be solved explicitly, but all that we care about is the fact that the solution is finite.

- 2. The optional sampling theorem applies, so  $\mathbb{E}(X_{\tau}) = \mathbb{E}(X_0) = 0$ .
- 3. Let  $q = \mathbb{P}(\tau_{-a} < \tau_b)$  so that  $1 q = \mathbb{P}(\tau_b < \tau_{-a})$ . By definition,  $X_{\tau} = -a$  if  $\tau_{-a} < \tau_b$  and  $X_{\tau} = b$  if  $\tau_b < \tau_{-a}$ . So from (b), q(-a) + (1 q)b = 0 and therefore q = b/(a + b).

So gambling until the net winnings either falls to -a or reaches b is a workable strategy, but alas has expected value 0. Here's another example that shows that the first version of the optional sampling theorem can fail if the stopping times are not bounded.

Suppose again that 
$$p = \frac{1}{2}$$
. Let  $a, b \in \mathbb{N}_+$  with  $a < b$ . Then  $\tau_a < \tau_b < \infty$  but

$$b = \mathbb{E}\left(X_{\tau_b} \mid \mathscr{F}_{\tau_a}\right) \neq X_{\tau_a} = a \tag{17.3.17}$$

Proof

Since  $X_0 = 0$ , the process X must reach a before reaching b. As before,  $\tau_b < \infty$  but  $\mathbb{E}(\tau_b) = \infty$  since X is a null recurrent Markov chain.

This result does not contradict the optional stopping theorem since the stopping times are not bounded.

#### Wald's Equation

*Wald's equation*, named for Abraham Wald is a formula for the expected value of the sum of a random number of independent, identically distributed random variables. We have considered this before, in our discussion of conditional expected value and our discussion of random samples, but martingale theory leads to a particularly simple and elegant proof.

Suppose that  $X = (X_n : n \in \mathbb{N}_+)$  is a sequence of independent, identically distributed variables with common mean  $\mu \in \mathbb{R}$ . If *N* is a stopping time for X with  $\mathbb{E}(N) < \infty$  then

$$\mathbb{E}\left(\sum_{k=1}^{N} X_k\right) = \mathbb{E}(N)\mu \tag{17.3.18}$$

Proof

Let  $\mathfrak{F}$  denote the natural filtration associated with X. Let  $c = \mathbb{E}(|X_n|)$ , so that by assumption,  $c < \infty$ . Finally, let

$$Y_n = \sum_{k=1}^n (X_k - \mu) \quad n \in \mathbb{N}_+$$
 (17.3.19)

Then  $\boldsymbol{Y} = (Y_n : n \in \mathbb{N}_+)$  is a martingale relative to  $\mathfrak{F}$ , with mean 0. Note that

$$\mathbb{E}(|Y_{n+1} - Y_n|) = \mathbb{E}(|X_{n+1} - \mu|) \le c + |\mu|, \quad n \in \mathbb{N}_+$$
(17.3.20)

Hence a discrete version of the optional stopping theorem applies and we have  $\mathbb{E}(Y_N) = 0$ . Therefore

$$0 = \mathbb{E}(Y_N) = \mathbb{E}\left[\sum_{k=1}^N (X_k - \mu)\right] = \mathbb{E}\left(\sum_{k=1}^N X_k - N\mu\right) = \mathbb{E}\left(\sum_{k=1}^N X_k\right) - \mathbb{E}(N)\mu$$
(17.3.21)

#### Patterns in Multinomial Trials

Patterns in multinomial trials were studied in the chapter on Renewal Processes. As is often the case, martingales provide a more elegant solution. Suppose that  $L = (L_1, L_2, ...)$  is a sequence of independent, identically distributed random variables taking values in a finite set S, so that L is a sequence of multinomial trials. Let f denote the common probability density function so that for a generic trial variable L, we have  $f(a) = \mathbb{P}(L = a)$  for  $a \in S$ . We assume that all outcomes in S are actually possible, so f(a) > 0 for  $a \in S$ .

In this discussion, we interpret *S* as an *alphabet*, and we write the sequence of variables in concatenation form,  $L = L_1 L_2 \cdots$  rather than standard sequence form. Thus the sequence is an infinite string of letters from our alphabet *S*. We are interested in the first occurrence of a particular finite substring of letters (that is, a "word" or "pattern") in the infinite sequence. The following definition will simplify the notation.

If  $\boldsymbol{a} = a_1 a_2 \cdots a_k$  is a word of length  $k \in \mathbb{N}_+$  from the alphabet S, define

$$f(a) = \prod_{i=1}^{k} f(a_i)$$
(17.3.22)

so f(a) is the probability of k consecutive trials producing word a.

So, fix a word  $a = a_1 a_2 \cdots a_k$  of length  $k \in \mathbb{N}_+$  from the alphabet S, and consider the number of trials  $N_a$  until a is completed. Our goal is compute  $\nu(a) = \mathbb{E}(N_a)$ . We do this by casting the problem in terms of a sequence of gamblers playing fair games and then using the optional stopping theorem above. So suppose that if a gambler bets  $c \in (0, \infty)$  on a letter  $a \in S$  on a trial, then the gambler wins c/f(a) if a occurs on that trial and wins 0 otherwise. The expected value of this bet is

$$f(a)\frac{c}{f(a)} - c = 0 \tag{17.3.23}$$

and so the bet is fair. Consider now a gambler with an initial fortune 1. When she starts playing, she bets 1 on  $a_1$ . If she wins, she bet her entire fortune  $1/f(a_1)$  on the next trial on  $a_2$ . She continues in this way: as long as she wins, she bets her entire fortune on the next trial on the next letter of the word, until either she loses or completes the word a. Finally, we consider a sequence of independent gamblers playing this strategy, with gambler i starting on trial i for each  $i \in \mathbb{N}_+$ .

For a finite word a from the alphabet S,  $\nu(a)$  is the total winnings by all of the players at time  $N_a$ .

Proof

Let  $X_n$  denote the total fortunes of all of the gamblers after trial  $n \in \mathbb{N}_+$ . Since all of the bets are fair,  $\mathbf{X} = \{X_n : n \in \mathbb{N}_+\}$  is a martingale with mean 0. We will show that the conditions in the discrete version of the optional sampling theorem hold. First, consider disjoint blocks of trials of length k, that is

$$((L_1, L_2, \dots, L_k), (L_{k+1}, L_{k+2}, \dots, L_{2k}), \dots)$$
 (17.3.24)

Let  $M_a$  denote the index of the first such block that forms the letter a. This variable has the geometric distribution on  $\mathbb{N}_+$  with success parameter f(a) and so in particular,  $\mathbb{E}(M_a) = 1/f(a)$ . But clearly  $N_a \leq kM_a$  so  $\nu(a) < k/f(a) < \infty$ . Next note that all of the gamblers have stopped playing by time N, so clearly  $|X_{n+1} - X_n| \leq 1/f(a)$  for  $n \in \mathbb{N}_+$ . So the optional stopping theorem applies, and hence  $\mathbb{E}(X_{N_a}) = 0$ . But note that  $\nu(a)$  can also be interpreted as the expected amount of money invested by the gamblers (1 unit at each time until the game ends at time  $N_a$ ), and hence this must also be the total winnings at time  $N_a$  (which is deterministic).

Given *a*, we can compute the total winnings precisely. By definition, trials N - k + 1, ..., N form the word *a* for the first time. Hence for  $i \le N - k$ , gambler *i* loses at some point. Also by definition, gambler N - k + 1 wins all of her bets, completes word *a* and so collects 1/f(a). The complicating factor is that gamblers N - k + 2, ..., N may or may not have won all of their bets at the point when the game ends. The following exercise illustrates this.

Suppose that L is a sequence of Bernoulli trials (so  $S = \{0, 1\}$ ) with success probability  $p \in (0, 1)$ . For each of the following strings, find the expected number of trials needed to complete the string.

1.001

2.010

Solution

Let q = 1 - p.

1. For the word 001, gambler N-2 wins  $\frac{1}{q^2p}$  on her three bets. Gambler N-2 makes two bets, winning the first but losing the second. Gambler N loses her first (and only) bet. Hence  $\nu(001) = \frac{1}{q^2p}$ 

2. For the word 010, gambler N-2 wins  $\frac{1}{q^{2}p}$  on her three bets as before. Gambler N-1 loses his first bet. Gambler N wins 1/q on his first (and only) bet. So  $\nu(010) = \frac{1}{a^{2}p} + \frac{1}{q}$ 

The difference between the two words is that the word in (b) has a *prefix* (a proper string at the beginning of the word) that is also a *suffix* (a proper string at the end of the word). Word a has no such prefix. Thus we are led naturally to the following dichotomy:

Suppose that *a* is a finite word from the alphabet *S*. If no proper prefix of *a* is also a suffix, then *a* is *simple*. Otherwise, *a* is *compound*.

Here is the main result, which of course is the same as when the problem was solved using renewal theory.

Suppose that  $\boldsymbol{a}$  is a finite word in the alphabet S.

1. If **a** is simple then  $\nu(\mathbf{a}) = 1/f(\mathbf{a})$ .

2. If *a* is compound, then  $\nu(a) = 1/f(a) + \nu(b)$  where *b* is the longest word that is both a prefix and a suffix of *a*.

Proof

The ingredients are in place from our previous discussion. Suppose that  $m{a}$  has length  $k \in \mathbb{N}_+$  .

- 1. If *a* is simple, only player N k + 1 wins, and she wins 1/f(a).
- 2. Suppose *a* is compound and *b* is the largest proper prefix-suffix. player N k + 1 wins 1/f(a) as always. The winnings of players N k + 2, ..., N are the same as the winnings of a new sequence of gamblers playing a new sequence of trials with the goal of reaching word *b*.

For a compound word, we can use (b) to reduce the computation to simple words.

Consider Bernoulli trials with success probability  $p \in (0, 1)$ . Find the expected number of trials until each of the following strings is completed.

1. 1011011 2. 11 · · · 1 (*k* times)

Solutions

Again, let q = 1 - p. 1.  $\nu(1011011) = \frac{1}{p^5q^2} + \nu(1011) = \frac{1}{p^5q^2} + \frac{1}{p^3q} + \nu(1) = \frac{1}{p^5q^2} + \frac{1}{p^3q} + \frac{1}{p}$ 2. Let  $\mathbf{1}_j$  denote a string of j 1s for  $j \in \mathbb{N}_+$ . If  $k \ge 2$  then  $\nu(\mathbf{1}_k) = 1/p^k + \nu(\mathbf{1}_{k-1})$ . Hence  $\nu(\mathbf{1}_k) = \sum_{j=1}^k \frac{1}{p^j}$ (17.3.25)

Recall that an *ace-six flat die* is a six-sided die for which faces 1 and 6 have probability  $\frac{1}{4}$  each while faces 2, 3, 4, and 5 have probability  $\frac{1}{8}$  each. Ace-six flat dice are sometimes used by gamblers to cheat.

Suppose that an ace-six flat die is thrown repeatedly. Find the expected number of throws until the pattern 6165616occurs. Solution

From our main theorem,

$$\begin{split} \nu(6165616) &= \frac{1}{f(6165616)} + \nu(616) = \frac{1}{f(6165616)} + \frac{1}{f(616)} + \nu(6) \\ &= \frac{1}{f(6165616)} + \frac{1}{f(616)} + \frac{1}{f(6)} = \frac{1}{(1/4)^6 (1/8)} + \frac{1}{(1/4)^3} + \frac{1}{1/4} = 32\,836 \end{split}$$

Suppose that a monkey types randomly on a keyboard that has the 26 lower-case letter keys and the space key (so 27 keys). Find the expected number of keystrokes until the monkey produces each of the following phrases:

it was the best of times
 to be or not to be

#### Solution

5010001 1.  $27^{24} \approx 2.258 \times 10^{34}$ 2.  $27^5 + 27^{18} \approx 5.815 \times 10^{25}$ 

### The Secretary Problem

The secretary problem was considered in the chapter on Finite Sampling Models. In this discussion we will solve a variation of the problem using martingales. Suppose that there are  $n \in \mathbb{N}_+$  candidates for a job, or perhaps potential marriage partners. The candidates arrive sequentially in random order and are interviewed. We measure the quality of each candidate by a number in the interval [0, 1]. Our goal is to select the very best candidate, but once a candidate is rejected, she cannot be recalled. Mathematically, our assumptions are that the sequence of candidate variables  $\mathbf{X} = (X_1, X_2, \ldots, X_n)$  is independent and that each is uniformly distributed on the interval [0, 1] (and so has the *standard uniform distribution*). Our goal is to select a stopping time  $\tau$  with respect to  $\mathbf{X}$  that maximizes  $\mathbb{E}(X_{\tau})$ , the expected value of the chosen candidate. The following sequence will play a critical role as a sequence of thresholds.

Define the sequence  $\boldsymbol{a} = (a_k : k \in \mathbb{N})$  by  $a_0 = 0$  and  $a_{k+1} = \frac{1}{2}(1 + a_k^2)$  for  $k \in \mathbb{N}$ . Then

1.  $a_k < 1$  for  $k \in \mathbb{N}$ . 2.  $a_k < a_{k+1}$  for  $k \in \mathbb{N}$ . 3.  $a_k \to 1$  as  $k \to \infty$ . 4. If X is uniformly distributed on [0, 1] then  $\mathbb{E}(X \lor a_k) = a_{k+1}$  for  $k \in \mathbb{N}$ . Proof 1. Note that  $a_1 = \frac{1}{2} < 1$ . Suppose that  $a_k < 1$  for some  $k \in \mathbb{N}_+$ . Then  $a_{k+1} = \frac{1}{2}(1 + a_k^2) < \frac{1}{2}(1 + 1) = 1$ 2. Note that  $0 = a_0 < a_1 = \frac{1}{2}$ . Suppose that  $a_k > a_{k-1}$  for some  $k \in \mathbb{N}_+$ . Then  $a_{k+1} = \frac{1}{2}(1 + a_k^2) < \frac{1}{2}(1 + a_{k-1}^2) = a_k$ . 3. Since the sequence is increasing and bounded above,  $a_\infty = \lim_{k \to \infty} a_k$  exists. Taking limits in the recursion relation gives  $a_\infty = \frac{1}{2}(1 + a_\infty^2)$  or equivalently  $(a_\infty - 1)^2 = 0$ .

4. For  $k \in \mathbb{N}$ ,

$$\mathbb{E}(X \lor a_k) = \int_0^1 (x \lor a_k) dx = \int_0^{a_k} a_k \, dx + \int_{a_k}^1 x \, dx = rac{1}{2}(1+a_k^2) = a_{k+1}$$
 (17.3.26)

Since  $a_0 = 0$ , all of the terms of the sequence are in [0, 1) by (a). Approximations of the first 10 terms are

$$(0, 0.5, 0.625, 0.695, 0.742, 0.775, 0.800, 0.820, 0.836, 0.850, 0.861, \ldots)$$
 (17.3.27)

Property (d) gives some indication of why the sequence is important for the secretary probelm. At any rate, the next theorem gives the solution. To simplify the notation, let  $\mathbb{N}_n = \{0, 1, ..., n\}$  and  $\mathbb{N}_n^+ = \{1, 2, ..., n\}$ .

The stopping time  $\tau = \inf \{k \in \mathbb{N}_n^+ : X_k > a_{n-k}\}\$  is optimal for the secretary problem with n candidates. The optimal value is  $\mathbb{E}(X_{\tau}) = a_n$ .

Proof

Let  $\mathfrak{F} = \{\mathscr{F}_k : k \in \mathbb{N}_n^+\}$  be the natural filtration of X, and suppose that  $\rho$  is a stopping time for  $\mathfrak{F}$ . Define  $Y = \{Y_k : k \in \mathbb{N}_n\}$  by  $Y_0 = 0$  and  $Y_k = X_{\rho \wedge k} \vee a_{n-k}$  for  $k \in \mathbb{N}_n^+$ . We will show that Y is a super-martingale with respect to  $\mathfrak{F}$ . First, on the event  $\rho \leq k-1$ ,

$$\mathbb{E}(Y_k \mid \mathscr{F}_{k-1}) = \mathbb{E}[(X_{\rho} \lor a_{n-k}) \mid \mathscr{F}_{k-1}] = X_{\rho} \lor a_{n-k} \le X_{\rho} \lor a_{n-k+1} = Y_{k-1}$$
(17.3.28)

where we have used the fact that  $X_{\rho}\mathbf{1}(\rho \leq k-1)$  is measurable with respect to  $\mathscr{F}_{k-1}$  and the fact that the sequence a is increasing. On the event  $\rho > k-1$ ,

$$\mathbb{E}(Y_k \mid \mathscr{F}_{k-1}) = \mathbb{E}(X_k \lor a_{n-k} \mid \mathscr{F}_{k-1}) = \mathbb{E}(X_k \lor a_{n-k}) = a_{n-k+1} \le Y_{k-1}$$
(17.3.29)

where we have used the fact that  $X_k$  and  $\mathscr{F}_{k-1}$  are independent, and part (d) of the previous result. Since Y is a supermartingale and  $\rho$  is bounded, the optional stopping theorem applies and we have

$$\mathbb{E}(X_{\rho}) \le \mathbb{E}(X_{\rho} \lor a_{n-\rho}) = \mathbb{E}(Y_{\rho}) \le E(Y_{0}) = a_{n}$$
(17.3.30)

so  $a_n$  is an upper bound on the expected value of the candidate chosen by the stopping time  $\rho$ .

Next, we will show that in the special case that  $\rho = \tau$ , the process Y is a martingale. On the event  $\tau \leq k-1$  we have  $\mathbb{E}(Y_k \mid \mathscr{F}_{k-1}) = X_\tau \lor a_{n-k}$  as before. But by definition,  $X_\tau \geq a_{n-\tau} \geq a_{n-k+1} \geq a_{n-k}$  so on this event,

$$\mathbb{E}(Y_k \mid \mathscr{F}_{k-1}) = X_{\tau} = X_{\tau} \lor a_{n-k+1} = Y_{k-1}$$
(17.3.31)

On the event  $\tau > k-1$  we have  $\mathbb{E}(Y_k \mid \mathscr{F}_{k-1}) = a_{n-k+1}$  as before. But on this event,  $Y_{k-1} = a_{n-k+1}$ . Now since Y is a martingale and  $\tau$  is bounded, the optional stopping theorem applies and we have

$$\mathbb{E}(X_{\tau}) = \mathbb{E}(X_{\tau} \lor a_{n-\tau}) = \mathbb{E}(Y_{\tau}) = \mathbb{E}(Y_0) = a_n \tag{17.3.32}$$

Here is a specific example:

For n = 5, the decision rule is as follows:

1. Select candidate 1 if  $X_1 > 0.742$ ; otherwise,

2. select candidate 2 if  $X_2 > 0.695$ ; otherwise,

3. select candidate 3 if  $X_3 > 0.625$ ; otherwise,

4. select candidate 4 if  $X_4 > 0.5$ ; otherwise,

5. select candidate 5.

The expected value of our chosen candidate is 0.775.

In our original version of the secretary problem, we could only observe the *relative ranks* of the candidates, and our goal was to maximize the probability of picking the best candidate. With n = 5, the optimal strategy is to let the first two candidates go by and then pick the first candidate after that is better than all previous candidates, if she exists. If she does not exist, of course, we must select candidate 5. The probability of picking the best candidate is 0.433

## 17.4: Inequalities

## **Basic Theory**

In this section, we will study a number of interesting inequalities associated with martingales and their sub-martingale and supermartingale cousins. These turn out to be very important for both theoretical reasons and for applications. You many need to review infimums and supremums.

### **Basic Assumptions**

As in the Introduction, we start with a stochastic process  $X = \{X_t : t \in T\}$  on an underlying probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ , having state space  $\mathbb{R}$ , and where the index set T (representing time) is either  $\mathbb{N}$  (discrete time) or  $[0, \infty)$  (continuous time). Next, we have a filtration  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$ , and we assume that X is *adapted* to  $\mathfrak{F}$ . So  $\mathfrak{F}$  is an increasing family of sub  $\sigma$ -algebras of  $\mathscr{F}$  and  $X_t$ is measurable with respect to  $\mathscr{F}_t$  for  $t \in T$ . We think of  $\mathscr{F}_t$  as the collection of events up to time  $t \in T$ . We assume that  $\mathbb{E}(|X_t|) < \infty$ , so that the mean of  $X_t$  exists as a real number, for each  $t \in T$ . Finally, in continuous time where  $T = [0, \infty)$ , we make the standard assumptions that  $t \mapsto X_t$  is right continuous and has left limits, and that the filtration  $\mathfrak{F}$  is right continuous and complete.

#### **Maximal Inequalites**

For motivation, let's review a modified version of Markov's inequality, named for Andrei Markov.

If X is a real-valued random variable then

$$\mathbb{P}(X \ge x) \le rac{1}{x} \mathbb{E}(X; X \ge x), \quad x \in (0, \infty)$$
 $(17.4.1)$ 

Proof

The modified version has essentially the same elegant proof as the original. Clearly

$$x\mathbf{1}(X \ge x) \le X\mathbf{1}(X \ge x), \quad x \in (0, \infty)$$
(17.4.2)

Taking expected values through the inequality gives  $x\mathbb{P}(X \ge x) \le \mathbb{E}(X; X \ge x)$ . Dividing both sides by x gives the result (and it is at this point that we need x > 0.).

So Markov's inequality gives an upper bound on the probability that X exceeds a given positive value x, in terms of a moment of X. Now let's return to our stochastic process  $\mathbf{X} = \{X_t : t \in T\}$ . To simplify the notation, let  $T_t = \{s \in T : s \leq t\}$  for  $t \in T$ . Here is the main definition:

For the process  $\boldsymbol{X}$ , define the corresponding *maximal process*  $\boldsymbol{U} = \{U_t : t \in T\}$  by

$$U_t = \sup\{X_s : s \in T_t\}, \quad t \in T$$

$$(17.4.3)$$

Clearly, the maximal process is increasing, so that if  $s, t \in T$  with  $s \leq t$  then  $U_s \leq U_t$ . A trivial application of Markov's inequality above would give

$$\mathbb{P}(U_t \ge x) \le rac{1}{x} \mathbb{E}(U_t; U_t \ge x), \quad x > 0$$

$$(17.4.4)$$

But when X is a sub-martingale, the following theorem gives a much stronger result by replacing the first occurrent of  $U_t$  on the right with  $X_t$ . The theorem is known as *Doob's sub-martingale maximal inequality* (or more simply as *Doob's inequality*), named once again for Joseph Doob who did much of the pioneering work on martingales. A sub-martingale has an *increasing property* of sorts in the sense that if  $s, t \in T$  with  $s \leq t$  then  $\mathbb{E}(X_t | \mathscr{F}_s) \geq X_s$ , so it's perhaps not entirely surprising that such a bound is possible.

Suppose that  $\boldsymbol{X}$  is a sub-martingale. For  $t \in T$ , let  $U_t = \sup\{X_s : s \in T_t\}$ . Then

$$\mathbb{P}(U_t \ge x) \le rac{1}{x} \mathbb{E}(X_t; U_t \ge x), \quad x \in (0,\infty)$$
 $(17.4.5)$ 

#### Proof in the discrete time

So  $T = \mathbb{N}$  and the maximal process is given by  $U_n = \max \{X_k : k \in \mathbb{N}_n\}$  for  $n \in \mathbb{N}$ . Let  $x \in (0, \infty)$ , and define  $\tau_x = \min\{k \in \mathbb{N} : X_k \ge x\}$  where as usual,  $\min(\emptyset) = \infty$ . The random time  $\tau_x$  is a stopping time relative to  $\mathfrak{F}$ . Moreover, the processes  $\{U_n : n \in \mathbb{N}\}$  and  $\{\tau_x : x \in (0, \infty)\}$  are inverses in the sense that for  $n \in \mathbb{N}$  and  $x \in (0, \infty)$ ,

$$U_n \ge x ext{ if and only if } au_x \le n ext{ (17.4.6)}$$

We have seen this type of duality before—in the Poisson process and more generally in renewal processes. Let  $n \in \mathbb{N}$ . First note that

$$\mathbb{E}\left(X_{\tau_x \wedge n}\right) = \mathbb{E}\left(X_{\tau_x \wedge n}; \tau_x \le n\right) + \mathbb{E}\left(X_{\tau_x \wedge n}; \tau_x > n\right) \tag{17.4.7}$$

If  $au_x \leq n$  then  $X_{ au_x \wedge n} = X_{ au_x} \geq x$  . On the other hand if  $au_x > n$  then  $X_{ au_x \wedge n} = X_n$  . So we have

$$\mathbb{E}\left(X_{\tau_x \wedge n}\right) \ge x \mathbb{P}(\tau_x \le n) + \mathbb{E}(X_n; \tau_x > n) = x \mathbb{P}(U_t \ge x) + \mathbb{E}(X_n; \tau_x > n)$$
(17.4.8)

Similarly,

$$\mathbb{E}(X_n) = \mathbb{E}(X_n; \tau_x \le n) + \mathbb{E}(X_n; \tau_x > n) = \mathbb{E}(X_n; U_t \ge x) + \mathbb{E}(X_n; \tau_x > n)$$
(17.4.9)

But by the optional stopping theorem,  $\mathbb{E}\left(X_{ au_x \wedge n}
ight) \leq \mathbb{E}(X_n)$  . Hence we have

$$x\mathbb{P}(U_t \ge x) + \mathbb{E}(X_n; \tau_x > n) \le \mathbb{E}(X_n; U_t \ge x) + \mathbb{E}(X_n; \tau_x > n)$$
(17.4.10)

Subtracting the common term and then dividing both sides by x gives the result

Proof in continuous time

For  $k \in \mathbb{N}$ , let  $\mathbb{D}_k^+ = \{j/2^k : j \in \mathbb{N}\}$  denote the set of nonnegative dyadic rationals (or *binary rationals*) of rank k or less. For  $t \in [0, \infty)$  let  $T_t^k = (\mathbb{D}_k^+ \cap [0, t]) \cup \{t\}$ , so that  $T_t^k$  is the finite set of such dyadic rationals that are less than t, with t added to the set. Note that  $T_t^k$  has an ordered enumeration, so  $\mathbf{X}^k = \{X_s : s \in T_t^k\}$  is a discrete-time sub-martingale for each  $k \in \mathbb{N}$ . Let  $U_t^k = \sup\{X_s : s \in T_t^k\}$  for  $k \in \mathbb{N}$ . Note that  $T_t^j \subset T_t^k \subset [0, t]$  for  $t \in [0, \infty)$  and for  $j, k \in \mathbb{N}$  with j < k and therefore  $U_t^j \leq U_t^k \leq U_t$ . It follows that for  $x \in (0, \infty)$ ,

$$\left\{U_t^j \ge x\right\} \subseteq \left\{U_t^k \ge x\right\} \subset \left\{U_t \ge x\right\}$$
(17.4.11)

The set  $\mathbb{D}^+$  of *all* nonnegative dyadic rationals is dense in  $[0, \infty)$  and so since X is right continuous and has left limits, it follows that if  $U_t \ge x$  then  $U_t^k \ge x$  for some  $k \in \mathbb{N}$ . That is, we have

$$\{U_t \ge x\} = \bigcup_{k=0}^{\infty} \{U_t^k \ge x\}$$
(17.4.12)

The maximal inequality applies to the discrete-time sub-martingale  $X^k$  and so

$$P(U_t^k \ge x) \le \frac{1}{x} \mathbb{E}(X_t; U_t^k \ge x)$$
(17.4.13)

for each  $k \in \mathbb{N}$ . By the monotone convergence theorem, the left side converges to  $\mathbb{P}(U_t \ge x)$  as  $k \to \infty$  and the right side converges to  $\mathbb{E}(X; U_t \ge x)$  as  $k \to \infty$ .

There are a number of simple corollaries of the maximal inequality. For the first, recall that the *positive part* of  $x \in \mathbb{R}$  is  $x^+ = x \lor 0$ , so that  $x^+ = x$  if x > 0 and  $x^+ = 0$  if  $x \le 0$ .

Suppose that  $oldsymbol{X}$  is a sub-martingale. For  $t \in T$  , let  $V_t = \sup\{X_s^+ : s \in T_t\}$  . Then

$$\mathbb{P}(V_t \ge x) \le rac{1}{x} \mathbb{E}(X_t^+; V_t \ge x), \quad x \in (0,\infty)$$
 $(17.4.14)$ 

Proof

Recall that since X is a sub-martingale and  $x \mapsto x^+$  is increasing and convex,  $X^+ = \{X_t^+ : t \in T\}$  is also a sub-martingale. Hence the result follows from the general maximal inequality for sub-martingales.

As a further simple corollary, note that

$$\mathbb{P}(V_t \ge x) \le rac{1}{x} \mathbb{E}(X_t^+), \quad x \in (0,\infty)$$
 $(17.4.15)$ 

This is sometimes how the maximal inequality is given in the literature.

Suppose that  $\boldsymbol{X}$  is a martingale. For  $t \in T$ , let  $W_t = \sup\{|X_s| : s \in T_t\}$ . Then

I

$$\mathbb{P}(W_t \ge x) \le rac{1}{x} \mathbb{E}(|X_t|; W_t \ge x), \quad x \in (0,\infty)$$
 $(17.4.16)$ 

Proof

Recall that since X is a martingale, and  $x \mapsto |x|$  is convex,  $|X| = \{|X_t| : t \in T\}$  is a sub-martingale. Hence the result follows from the general maximal inequality for sub-martingales.

Once again, a further simple corollary is

$$\mathbb{P}(W_t \geq x) \leq rac{1}{x}\mathbb{E}(|X_t|), \quad x \in (0,\infty)$$
 $(17.4.17)$ 

Next recall that for  $k \in (1, \infty)$ , the *k*-norm of a real-valued random variable *X* is  $||X||_k = \left[\mathbb{E}(|X|^k)\right]^{1/k}$ , and the vector space  $\mathscr{L}_k$  consists of all real-valued random variables for which this norm is finite. The following theorem is the *norm version* of the Doob's maximal inequality.

Suppose again that  $m{X}$  is a martingale. For  $t \in T$ , let  $W_t = \sup\{|X_s| : s \in T_t\}$  . Then for k > 1,

$$\|W_t\|_k \le \frac{k}{k-1} \|X_t\|_k \tag{17.4.18}$$

Proof

Fix  $t \in T$ . If  $\mathbb{E}(|X_t|^k) = \infty$ , the inequality trivial holds, so assume that  $\mathbb{E}(|X_t|^k) < \infty$ , and thus that  $X_t \in \mathscr{L}_k$ . The proof relies fundamentally on Hölder's inequality, and for that inequality to work, we need to truncate the variable  $W_t$  and consider instead the the bounded random variable  $W_t \wedge c$  where  $c \in (0, \infty)$ . First we need to show that

$$\mathbb{P}(W_t \wedge c \ge x) \le rac{1}{x} \mathbb{E}(|X_t|; W_t \wedge c \ge x), \quad x \in (0, \infty)$$

$$(17.4.19)$$

If c < x , both sides are 0. If  $c \ge x$  ,  $\{W_t \land c \ge x\} = \{W_t \ge x\}$  and so from the maximal inequality above,

$$\mathbb{P}(W_t \wedge c \ge x) = \mathbb{P}(W_t \ge x) \le \frac{1}{x} \mathbb{E}(|X_t|; W_t \ge x) = \mathbb{E}(|X_t|; W_t \wedge c \ge x)$$
(17.4.20)

Next recall that

$$\|W_t \wedge c\|_k^k = \mathbb{E}[(W_t \wedge c)^k] = \int_0^\infty k x^{k-1} \mathbb{P}(W_t \wedge c \ge x) dx$$
 (17.4.21)

Applying the inequality gives

$$\mathbb{E}[(W_t \wedge c)^k] \leq \int_0^\infty k x^{k-2} \mathbb{E}[|X_t|; W_t \wedge c \geq x] dx$$
 (17.4.22)

By Fubini's theorem we can interchange the expected value and the integral which gives

$$\mathbb{E}[(W_t \wedge c)^k] \le \mathbb{E}\left[\int_0^{W_t \wedge c} kx^{k-2} |X_t| dx\right] = \frac{k}{k-1} \mathbb{E}[|X_t| (W_t \wedge c)^{k-1}]$$
(17.4.23)

But  $X_t \in \mathscr{L}_k$  and  $(W_t \wedge c)^{k-1} \in \mathscr{L}_j$  where j = k/(k-1) is the exponent conjugate to k. So an application of Hölder's inequality gives

$$\|W_t \wedge c\|_k^k \le \frac{k}{k-1} \|X_t\|_k \, \|(W_t \wedge c)^{k-1}\|_j = \frac{k}{k-1} \|X_t\|_k \|W_t \wedge c\|_k^{k-1} \tag{17.4.24}$$

where we have used the simple fact that  $\|(W_t \wedge c)^{k-1}\|_j = \|W_t \wedge c\|_k^{k-1}$ . Dividing by this factor gives

$$\|W_t \wedge c\|_k \le rac{k}{k-1} \|X_t\|_k$$
 (17.4.25)

Finally,  $||W_t \wedge c||_k \uparrow ||W_t||_k$  as  $c \to \infty$  by the monotone convergence theorem. So letting  $c \to \infty$  in the last displayed equation gives

$$\|W_t\|_k \le \frac{k}{k-1} \|X_t\|_k \tag{17.4.26}$$

Once again,  $W = \{W_t : t \in T\}$  is the maximal process associated with  $|X| = \{|X_t| : t \in T\}$ . As noted in the proof, j = k/(k-1) is the exponent *conjugate* to k, satisfying 1/j+1/k=1. So this version of the maximal inequality states that the k norm of the maximum of the martingale X on  $T_t$  is bounded by j times the k norm of  $X_t$ , where j and k are conjugate exponents. Stated just in terms of expected value, rather than norms, the  $\mathscr{L}_k$  maximal inequality is

$$\mathbb{E}\left(\left|W_{t}\right|^{k}
ight) \leq \left(rac{k}{k-1}
ight)^{k}\mathbb{E}\left(\left|X_{t}
ight|^{k}
ight)$$
(17.4.27)

Our final result in this discussion is a variation of the maximal inequality for super-martingales.

Suppose that  $m{X} = \{X_t : t \in T\}$  is a nonnegative super-martingale, and let  $U_\infty = \sup\{X_t : t \in T\}$  . Then

$$\mathbb{P}(U_\infty \ge x) \le rac{1}{x} \mathbb{E}(X_0), \quad x \in (0,\infty)$$
 (17.4.28)

Proof

Let  $Y_t = -X_t$  for  $t \in T$ . Since X is a super-martingale, Y is a sub-martinagle. And since X is nonnegative,  $Y_t^+ = X_t$  for  $t \in T$ . Let  $U_t = \sup\{X_s : s \in T_t\} = \sup\{Y_s^+ : s \in T_t\}$  for  $t \in T$ . By the maximal inequality for sub-martingales, and since X is a super-martingale we have for  $t \in T$ ,

$$\mathbb{P}(U_t \ge x) \le \frac{1}{x} \mathbb{E}(Y_t^+) = \frac{1}{x} \mathbb{E}(X_t) \le \frac{1}{x} \mathbb{E}(X_0), \quad x \in (0, \infty)$$
(17.4.29)

Next note that  $U_t \uparrow U_\infty$  as  $t \to \infty$ . Let  $x \in (0, \infty)$  and  $\epsilon \in (0, x)$ . If  $U_\infty \ge x$  then  $U_t \ge x - \epsilon$  for sufficiently large  $t \in T$ . Hence

$$\{U_{\infty} \ge x\} \subseteq \bigcup_{k=1}^{\infty} \{U_k \ge x - \epsilon\}$$
 (17.4.30)

Using the continuity theorem for increasing events, and our result above we have

$$\mathbb{P}(U_{\infty} \ge x) \le \lim_{k \to \infty} \mathbb{P}(U_k \ge x - \epsilon) \le rac{1}{x - \epsilon} \mathbb{E}(X_0)$$
(17.4.31)

Since this holds for all  $\epsilon \in (0, x)$ , it follows that  $\mathbb{P}(U_{\infty} \geq x) \leq \frac{1}{x} \mathbb{E}(X_0)$ .

#### The Up-Crossing Inequality

The up-crossing inequality gives a bound on how much a sub-martingale (or super-martingale) can oscillate, and is the main tool in the martingale convergence theorems that will be studied in the next section. It should come as no surprise by now that the inequality is due to Joseph Doob. We start with the discrete-time case.

Suppose that  $\boldsymbol{x} = (x_n : n \in \mathbb{N})$  is a sequence of real numbers, and that  $a, b \in \mathbb{R}$  with a < b. Define  $t_0(\boldsymbol{x}) = 0$  and then recursively define

$$egin{aligned} s_{k+1}(oldsymbol{x}) &= \inf\{n \in \mathbb{N}: n \geq t_k(oldsymbol{x}), x_n \leq a\}, \quad k \in \mathbb{N} \ t_{k+1}(oldsymbol{x}) &= \inf\{n \in \mathbb{N}: n \geq s_{k+1}(oldsymbol{x}), x_n \geq b\}, \quad k \in \mathbb{N} \end{aligned}$$

1. The *number of up-crossings* of the interval [a, b] by the sequence  $m{x}$  up to time  $n \in \mathbb{N}$  is

$$u_n(a,b,\boldsymbol{x}) = \sup\{k \in \mathbb{N} : t_k(\boldsymbol{x}) \le n\}$$
(17.4.32)

2. The *total number of up-crossings* of the interval [a, b] by the sequence  $\boldsymbol{x}$  is

$$u_{\infty}(a,b,\boldsymbol{x}) = \sup\{k \in \mathbb{N} : t_k(\boldsymbol{x}) < \infty\}$$
(17.4.33)

Details

As usual, we define  $\inf(\emptyset) = \infty$ . Note that if  $t_k(\boldsymbol{x}) < \infty$  for  $k \in \mathbb{N}_+$ , then  $(x_n : n = s_k(\boldsymbol{x}), \dots, t_k(\boldsymbol{x}))$  is the *k*th up-crossing of the interval [a, b] by the sequence  $\boldsymbol{x}$ .

So informally, as the name suggests,  $u_n(a, b, x)$  is the number of times that the sequence  $(x_0, x_1, \ldots, x_n)$  goes from a value below a to one above b, and u(a, b, x) is the number of times the entire sequence x goes from a value below a to one above b. Here are a few of simple properties:

Suppose again that  $\boldsymbol{x} = (x_n : n \in \mathbb{N})$  is a sequence of real numbers and that  $a, b \in \mathbb{R}$  with a < b. 1.  $u_n(a, b, \boldsymbol{x})$  is increasing in  $n \in \mathbb{N}$ . 2.  $u_n(a, b, \boldsymbol{x}) \to u(a, b, \boldsymbol{x})$  as  $n \to \infty$ . 3. If  $c, d \in \mathbb{R}$  with a < c < d < b then  $u_n(c, d, \boldsymbol{x}) \ge u_n(a, b, \boldsymbol{x})$  for  $n \in \mathbb{N}$ , and  $u(c, d, \boldsymbol{x}) \ge u(a, b, \boldsymbol{x})$ . Proof 1. Note that  $\{k \in \mathbb{N} : t_k(\boldsymbol{x}) \le n\} \subseteq \{k \in \mathbb{N} : t_k(\boldsymbol{x}) \le n+1\}$ . 2. Note that  $\bigcup_{n=0}^{\infty} \{k \in \mathbb{N} : t_k(\boldsymbol{x}) \le n\} = \{k \in \mathbb{N} : t_k(\boldsymbol{x}) \le \infty\}$ .

3. Every up-crossing of [a, b] is also an up-crossing of [c, d].

The importance of the definitions is found in the following theorem. Recall that  $\mathbb{R}^* = \mathbb{R} \cup \{-\infty, \infty\}$  is the set of extended real numbers, and  $\mathbb{Q}$  is the set of rational real numbers.

Suppose again that  $\boldsymbol{x} = (x_n : n \in \mathbb{N})$  is a sequence of real numbers. Then  $\lim_{n \to \infty} x_n$  exists in  $\mathbb{R}^*$  is and only if  $u_{\infty}(a, b, \boldsymbol{x}) < \infty$  for every  $a, b \in \mathbb{Q}$  with a < b.

Proof

We prove the contrapositive. Note that the following statements are equivalent:

- 1.  $\lim_{n\to\infty} x_n$  does not exist in in  $\mathbb{R}^*$ .
- 2.  $\liminf_{n \to \infty} x_n < \limsup_{n \to \infty} x_n$  .
- 3. There exists  $a, b \in \mathbb{Q}$  with a < b and with  $x_n \leq a$  for infinitely many  $n \in \mathbb{N}$  and  $x_n \geq b$  for infinitely many  $n \in \mathbb{N}$ .
- 4. There exists  $a, \, b \in \mathbb{Q}$  with  $a < b\,$  and  $u_\infty(a,b,oldsymbol{x}) = \infty$  .

Clearly the theorem is true with  $\mathbb{Q}$  replaced with  $\mathbb{R}$ , but the countability of  $\mathbb{Q}$  will be important in the martingale convergence theorem. As a simple corollary, if  $\boldsymbol{x}$  is bounded and  $u_{\infty}(a, b, \boldsymbol{x}) < \infty$  for every  $a, b \in \mathbb{Q}$  with a < b, then  $\boldsymbol{x}$  converges in  $\mathbb{R}$ . The up-crossing inequality for a discrete-time martingale  $\boldsymbol{X}$  gives an upper bound on the expected number of up-crossings of  $\boldsymbol{X}$  up to time  $n \in \mathbb{N}$  in terms of a moment of  $X_n$ .

Suppose that  $X = \{X_n : n \in \mathbb{N}\}$  satisfies the basic assumptions with respect to the filtration  $\mathfrak{F} = \{\mathscr{F}_n : n \in \mathbb{N}\}$ , and let  $a, b \in \mathbb{R}$  with a < b. Let  $U_n = u_n(a, b, X)$ , the random number of up-crossings of [a, b] by X up to time  $n \in \mathbb{N}$ .

1. If  $\boldsymbol{X}$  is a super-martingale relative to  $\mathfrak{F}$  then

$$\mathbb{E}(U_n) \le \frac{1}{b-a} \mathbb{E}[(X_n - a)^-] \le \frac{1}{b-a} \left[ \mathbb{E}(X_n^-) + |a| \right] \le \frac{1}{b-a} \left[ \mathbb{E}(|X_n|) + |a| \right], \quad n \in \mathbb{N}$$
(17.4.34)

2. If  $\boldsymbol{X}$  is a sub-martingale relative to  $\mathfrak{F}$  then

$$\mathbb{E}(U_n) \le \frac{1}{b-a} \mathbb{E}[(X_n - a)^+] \le \frac{1}{b-a} \left[ \mathbb{E}(X_n^+) + |a| \right] \le \frac{1}{b-a} \left[ \mathbb{E}(|X_n|) + |a| \right], \quad n \in \mathbb{N}$$
(17.4.35)

Proof

In the context of the up-crossing definition above, let  $\sigma_k = s_k(\mathbf{X})$  and  $\tau_k = t_k(\mathbf{X})$ . These are the random times that define the up-crossings of  $\mathbf{X}$ . Let  $Y_k = X_{\tau_k \wedge n} - X_{\sigma_k \wedge n}$  and then define  $Z_n = \sum_{k=1}^n Y_k$ . To understand the sum, let's take cases for the *k*th term  $Y_k$ :

- If  $\tau_k \leq n$  then  $Y_k = X_{\tau_k} X_{\sigma_k} \geq b a$  . By definition, the first  $U_n$  terms are of this form.
- If  $\sigma_k \leq n < \tau_k$  then  $Y_k = X_n X_{\sigma_k} \geq X_n a$  . There is at most one such term, with index  $k = U_n + 1$  .
- If  $\sigma_k > n$  then  $Y_k = X_n X_n = 0$  .

Hence  $Z_n \ge (b-a)U_n + (X_n - a)\mathbf{1} (\sigma_{U_n+1} \le n)$  and so  $(b-a)U_n \le Z_n - (X_n - a)\mathbf{1} (\sigma_{U_n+1} \le n)$  Next note that  $\sigma_k \wedge n$  and  $\tau_k \wedge n$  are bounded stopping times and of course  $\sigma_k \wedge n \le \tau_k \wedge n$ .

1. If *X* is a super-martingale, it follows from the optional stopping theorem that

$$\mathbb{E}(Y_k) = \mathbb{E}\left(X_{\tau_k \wedge n}\right) - \mathbb{E}\left(X_{\sigma_k \wedge n}\right) \le 0 \tag{17.4.36}$$

and therefore  $\mathbb{E}(Z_n) \leq 0$  . Finally,  $-(X_n - a)\mathbf{1}$   $(\sigma_{U_n + 1} \leq n) \leq (X_n - a)^-$  . Taking expected values gives

$$(b-a)\mathbb{E}(U_n) \le \mathbb{E}(Z_n) + \mathbb{E}[(X_n-a)^-] \le \mathbb{E}[(X_n-a)^-]$$
 (17.4.37)

The remaining parts of the inequality follow since  $(x-a)^- \leq x^- + |a| \leq |x|+|a| \quad ext{for } x \in \mathbb{R}$  .

Additional details

The process  $\mathbf{Z} = \{Z_n : n \in \mathbb{N}\}$  in the proof can be viewed as a transform of  $\mathbf{X} = \{X_n : n \in \mathbb{N}\}$  by a predictable process. Specifically, for  $n \in \mathbb{N}_+$ , let  $I_n = 1$  if  $\sigma_k < n \le \tau_k$  for some  $k \in \mathbb{N}$ , and let  $I_n = 0$  otherwise. Since  $\sigma_k$  and  $\tau_k$  are stopping times, note that  $\{I_n = 1\} \in \mathscr{F}_{n-1}$  for  $n \in \mathbb{N}_+$ . Hence the process  $\mathbf{I} = \{I_n : n \in \mathbb{N}_+\}$  is predictable with respect to  $\mathfrak{F}$ . Moreover, the transform of  $\mathbf{X}$  by  $\mathbf{I}$  is

$$(\boldsymbol{I} \cdot \boldsymbol{X})_n = \sum_{j=1}^n I_j (X_j - X_{j-1}) = \sum_{k=1}^n (X_{\tau_k \wedge n} - X_{\sigma_k \wedge n}) = Z_n, \quad n \in \mathbb{N}$$
(17.4.38)

Since I is a nonnegative process, if X is a martingale (sub-martingale, super-martingale), then  $I \cdot X$  is also a martingale (sub-martingale, super-martingale).

Of course if X is a martingale with respect to  $\mathfrak{F}$  then both inequalities apply. In continuous time, as usual, the concepts are more complicated and technical.

Suppose that  $oldsymbol{x} : [0,\infty) o \mathbb{R}$  and that that  $a, \ b \in \mathbb{R}$  with a < b.

1. If  $I \subset [0, \infty)$  is finite, define  $t_0^I(\boldsymbol{x}) = 0$  and then recursively define

$$egin{aligned} &s^I_{k+1}(oldsymbol{x}) &= \inf\left\{t \in I: t \geq t^I_k(oldsymbol{x}), x_t \leq a
ight\}, \quad k \in \mathbb{N} \ &t^I_{k+1}(oldsymbol{x}) &= \inf\left\{t \in I: t \geq s^I_{k+1}(oldsymbol{x}), x_t \geq b
ight\}, \quad k \in \mathbb{N} \end{aligned}$$

The *number of up-crossings* of the interval [a, b] by the function  $\boldsymbol{x}$  restricted to I is

$$u_I(a, b, \boldsymbol{x}) = \sup\left\{k \in \mathbb{N} : t_k^I(\boldsymbol{x}) < \infty\right\}$$
(17.4.39)

2. If  $I \subseteq [0, \infty)$  is infinite, the number of up-crossings of the interval [a, b] by  $\boldsymbol{x}$  restricted to I is

$$u_I(a, b, \boldsymbol{x}) = \sup\{u_J(a, b, \boldsymbol{x}) : J \text{ is finite and } J \subset I\}$$
(17.4.40)

To simplify the notation, we will let  $u_t(a, b, \boldsymbol{x}) = u_{[0,t]}(a, b, \boldsymbol{x})$ , the number of up-crossings of [a, b] by  $\boldsymbol{x}$  on [0, t], and  $u_{\infty}(a, b, \boldsymbol{x}) = u_{[0,\infty)}(a, b, \boldsymbol{x})$ , the total number of up-crossings of [a, b] by  $\boldsymbol{x}$ . In continuous time, the definition of up-crossings is built out of finte subsets of  $[0, \infty)$  for measurability concerns, which arise when we replace the deterministic function  $\boldsymbol{x}$  with a stochastic process  $\boldsymbol{X}$ . Here are the simple properties that are analogous to our previous ones.

Suppose again that  $oldsymbol{x}: [0,\infty) o \mathbb{R}$  and that  $a, \ b \in \mathbb{R}$  with a < b .

1. If 
$$I, \, J \subseteq [0,\infty)$$
 with  $I \subseteq J$  , then  $u_I(a,b,oldsymbol{x}) \leq u_J(a,b,oldsymbol{x})$ 

2. If  $(I_n : n \in \mathbb{N})$  is an increasing sequence of sets in  $[0, \infty)$  and  $J = \bigcup_{n=0}^{\infty} I_n$  then  $u_{I_n}(a, b, \boldsymbol{x}) \to u_J(a, b, \boldsymbol{x})$  as  $n \to \infty$ . 3. If  $c, d \in \mathbb{R}$  with a < c < d < b and  $I \subset [0, \infty)$  then  $u_I(c, d, \boldsymbol{x}) \ge u_I(a, b, \boldsymbol{x})$ .

Proof

1. The result follows easily from the definitions if I is finite (and J either finite or infinite). If I is infinite (and hence so is J), note that

 $\{u_K(a, b, \boldsymbol{x}) : K \text{ is finite and } K \subseteq I\} \subseteq \{u_K(a, b, \boldsymbol{x}) : K \text{ is finite and } K \subseteq J\}$ (17.4.41)

- 2. Since  $I_n$  is increasing in  $n \in \mathbb{N}$  (in the subset partial order), note that if  $K \subset [0, \infty)$  is finite, then  $K \subseteq J$  if and only if  $K \subseteq I_n$  for some  $n \in \mathbb{N}$ .
- 3. Every up-crossing of [a, b] is an up-crossing of [c, d].

The following result is the reason for studying up-crossings in the first place. Note that the definition built from finite set is sufficient.

Suppose that  $\boldsymbol{x} : [0, \infty) \to \mathbb{R}$ . Then  $\lim_{t \to \infty} x_t$  exists in  $\mathbb{R}^*$  if and only if  $u_{\infty}(a, b, \boldsymbol{x}) < \infty$  for every  $a, b \in \mathbb{Q}$  with a < b. Proof

As in the discrete-time case, we prove the contrapositive. The proof is almost the same: The following statements are equivalent:

- 1.  $\lim_{t\to\infty} x_t$  does not exist in in  $\mathbb{R}^*$ .
- 2.  $\liminf_{t \to \infty} x_t < \limsup_{t \to \infty} x_t$  .
- 3. There exists  $a, b \in \mathbb{Q}$  with a < b and there exists  $s_n, t_n \in [0, \infty)$  with  $x_{s_n} \leq a$  for  $n \in \mathbb{N}$  and  $x_{t_n} \geq b$  for  $n \in \mathbb{N}$ .
- 4. There exists  $a, \ b \in \mathbb{Q}$  with a < b and  $u_\infty(a, b, \boldsymbol{x}) = \infty$  .

Finally, here is the up-crossing inequality for martingales in continuous time. Once again, the inequality gives a bound on the expected number of up-crossings.

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  satisfies the basic assumptions with respect to the filtration  $\mathfrak{F} = \{\mathscr{F}_t : t \in [0, \infty)\}$ , and let  $a, b \in \mathbb{R}$  with a < b. Let  $U_t = u_t(a, b, X)$ , the random number of up-crossings of [a, b] by X up to time  $t \in [0, \infty)$ .

1. If  $\boldsymbol{X}$  is a super-martingale relative to  $\mathfrak{F}$  then

$$\mathbb{E}(U_t) \le \frac{1}{b-a} \mathbb{E}[(X_t - a)^-] \le \frac{1}{b-a} \left[ \mathbb{E}(X_t^-) + |a| \right] \le \frac{1}{b-a} \left[ \mathbb{E}(|X_t|) + |a| \right], \quad t \in [0, \infty) \quad (17.4.42)$$

2. If  $\boldsymbol{X}$  is a sub-martingale relative to  $\mathfrak{F}$  then

$$\mathbb{E}(U_t) \le \frac{1}{b-a} \mathbb{E}[(X_t - a)^+] \le \frac{1}{b-a} \big[ \mathbb{E}(X_t^+) + |a| \big] \le \frac{1}{b-a} \big[ \mathbb{E}(|X_t|) + |a| \big], \quad t \in [0,\infty) \quad (17.4.43)$$

Proof

Suppose that X is a sub-martingale; the proof for a super-martingale is analogous. Fix  $t \in [0, \infty)$  and  $a, b \in \mathbb{R}$  with a < b. For  $I \subseteq [0, \infty)$  let  $U_I = u_I(a, b, X)$ , the number of up-crossings of [a, b] by X restricted to I. Suppose that I is finite and that  $t \in I$  is the maximum of I. Since X restricted to I is also a sub-martingale, the discrete-time up-crossing theorem applies and so

$$\mathbb{E}(U_I) \le \frac{1}{b-a} \mathbb{E}[(X_t - a)^+]$$
(17.4.44)

Since  $U_t = \sup\{U_I : I \text{ is finite and } I \subset [0, t]\}$ , there exists finite  $I_n$  for  $n \in \mathbb{N}$  with  $U_{I_n} \uparrow U_t$  as  $n \to \infty$ . In particular,  $U_t$  is measurable. By property (a) in the theorem above, there exists such a sequence with  $I_n$  increasing in n and  $t \in I_n$  for each  $n \in \mathbb{N}$ . By the monotone convergence theorem,  $\mathbb{E}(U_{I_n}) \to \mathbb{E}(U_t)$  as  $n \to \infty$ . So by the displayed equation above,

$$\mathbb{E}(U_t) \le \frac{1}{b-a} \mathbb{E}[(X_t - a)^+]$$
(17.4.45)

#### **Examples and Applications**

#### Kolmogorov's Inequality

Suppose that  $X = \{X_n : n \in \mathbb{N}_+\}$  is a sequence of independent variables with  $\mathbb{E}(X_n) = 0$  and  $\operatorname{var}(X_n) = \mathbb{E}(X_n^2) < \infty$  for  $n \in \mathbb{N}_+$ . Let  $Y = \{Y_n : n \in \mathbb{N}\}$  be the partial sum process associated with X, so that

$$Y_n = \sum_{i=1}^n X_i, \quad n \in \mathbb{N}$$
(17.4.46)

From the Introduction we know that *Y* is a martingale. A simple application of the maximal inequality gives the following result, which is known as *Kolmogorov's inequality*, named for Andrei Kolmogorov.

For 
$$n \in \mathbb{N}$$
, let  $U_n = \max \{ |Y_i| : i \in \mathbb{N}_n \}$ . Then

$$\mathbb{P}(U_n \ge x) \le rac{1}{x^2} \mathrm{var}(Y_n) = rac{1}{x^2} \sum_{i=1}^n \mathbb{E}(X_i^2), \quad x \in (0,\infty)$$
 (17.4.47)

Proof

As noted above,  $\mathbf{Y}$  is a martingale. Since the function  $x \mapsto x^2$  on  $\mathbb{R}$  is convex,  $\mathbf{Y}^2 = \{Y_n^2 : n \in \mathbb{N}\}$  is a sub-martingale. Let  $V_n = \max\{Y_i^2 : i \in \mathbb{N}_n\}$  for  $n \in \mathbb{N}$ , and let  $x \in (0, \infty)$ . Applying the maximal inequality for sub-martingales we have

$$\mathbb{P}(U_n \ge x) = \mathbb{P}(V_n \ge x^2) \le \frac{1}{x^2} \mathbb{E}(Y_n^2) = \frac{1}{x^2} \operatorname{var}(Y_n)$$
(17.4.48)

Finally, since  $\boldsymbol{X}$  is an independent sequence,

$$\operatorname{var}(Y_n) = \sum_{i=1}^n \operatorname{var}(X_i) = \sum_{i=1}^n \mathbb{E}(X_i^2)$$
 (17.4.49)

#### Red and Black

In the game of red and black, a gambler plays a sequence of Bernoulli games with success parameter  $p \in (0, 1)$  at even stakes. The gambler starts with an initial fortune x and plays until either she is ruined or reaches a specified target fortune a, where  $x, a \in (0, \infty)$  with x < a. When  $p \le \frac{1}{2}$ , so that the games are fair or unfair, an optimal strategy is *bold play*: on each game, the gambler bets her entire fortune or just what is needed to reach the target, whichever is smaller. In the section on bold play we showed that when  $p = \frac{1}{2}$ , so that the games are fair, the probability of winning (that is, reaching the target a starting with x) is x/a. We can use the maximal inequality for super-martingales to show that indeed, one cannot do better.

To set up the notation and review various concepts, let  $X_0$  denote the gambler's initial fortune and let  $X_n$  denote the outcome of game  $n \in \mathbb{N}_+$ , where 1 denotes a win and -1 a loss. So  $\{X_n : n \in \mathbb{N}\}$  is a sequence of independent variables with  $\mathbb{P}(X_n = 1) = p$  and  $\mathbb{P}(X_n = -1) = 1 - p$  for  $n \in \mathbb{N}_+$ . (The initial fortune  $X_0$  has an unspecified distribution on  $(0, \infty)$ .) The gambler is at a casino after all, so of course  $p \leq \frac{1}{2}$ . Let

$$Y_n = \sum_{i=0}^n X_i, \quad n \in \mathbb{N}$$
(17.4.50)

so that  $Y = \{Y_n : n \in \mathbb{N}\}$  is the partial sum process associated with  $X = \{X_n : n \in \mathbb{N}\}$ . Recall that Y is also known as the *simple random walk* with parameter p, and since  $p \leq \frac{1}{2}$ , is a super-martingale. The process  $\{X_n : n \in \mathbb{N}_+\}$  is the *difference sequence* associated with Y. Next let  $Z_n$  denote the amount that the gambler bets on game  $n \in \mathbb{N}_+$ . The process  $Z = \{Z_n : n \in \mathbb{N}_+\}$  is *predictable* with respect to  $X = \{X_n : n \in \mathbb{N}\}$ , so that  $Z_n$  is measurable with respect to  $\sigma\{X_0, X_1, \ldots, X_{n-1}\}$  for  $n \in \mathbb{N}_+$ . So the gambler's fortune after n games is

$$W_n = X_0 + \sum_{i=1}^n Z_i X_i = X_0 + \sum_{i=1}^n Z_i (Y_i - Y_{i-1})$$
(17.4.51)

Recall that  $W = \{W_n : n \in \mathbb{N}\}$  is the *transform* of Z with Y, denoted  $W = Z \cdot Y$ . The gambler is not allowed to go into debt and so we must have  $Z_n \leq W_{n-1}$  for  $n \in \mathbb{N}_+$ : the gambler's bet on game n cannot exceed her fortune after game n-1. What's the probability that the gambler can ever reach or exceed the target a starting with fortune x < a?

Let 
$$U_\infty = \sup\{W_n: n \in \mathbb{N}\}$$
 . Suppose that  $x, \ a \in (0,\infty)$  with  $x < a$  and that  $X_0 = x$  . Then $\mathbb{P}(U_\infty > a) < rac{x}{2}$  (17.4.52)

Proof

Since *Y* is a super-martingale and *Z* is nonnegative, the transform  $W = Z \cdot Y$  is also a super-martingale. By the inequality for nonnegative super-martingales above:

$$\mathbb{P}(U_{\infty} \ge a) \le \frac{1}{a} \mathbb{E}(W_0) = \frac{x}{a}$$
(17.4.53)

Note that the only assumptions made on the gambler's sequence of bets Z is that the sequence is predictable, so that the gambler cannot see into the future, and that gambler cannot go into debt. Under these basic assumptions, no strategy can do any better than bold play. However, there *are* strategies that do as well as bold play; these are variations on bold play.

Open the simulation of the red and black game. Select bold play and  $p = \frac{1}{2}$ . Play the game with various values of initial and target fortunes.

## 17.5: Convergence

## **Basic Theory**

#### **Basic Assumptions**

As in the Introduction, we start with a stochastic process  $X = \{X_t : t \in T\}$  on an underlying probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ , having state space  $\mathbb{R}$ , and where the index set T (representing time) is either  $\mathbb{N}$  (discrete time) or  $[0, \infty)$  (continuous time). Next, we have a filtration  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$ , and we assume that X is *adapted* to  $\mathfrak{F}$ . So  $\mathfrak{F}$  is an increasing family of sub  $\sigma$ -algebras of  $\mathscr{F}$  and  $X_t$  is measurable with respect to  $\mathscr{F}_t$  for  $t \in T$ . We think of  $\mathscr{F}_t$  as the collection of events up to time  $t \in T$ . We assume that  $\mathbb{E}(|X_t|) < \infty$ , so that the mean of  $X_t$  exists as a real number, for each  $t \in T$ . Finally, in continuous time where  $T = [0, \infty)$ , we need the additional assumptions that  $t \mapsto X_t$  is right continuous and has left limits, and that the filtration  $\mathfrak{F}$  is standard (that is, right continuous and complete). Recall also that  $\mathscr{F}_{\infty} = \sigma \left(\bigcup_{t \in T} \mathscr{F}_t\right)$ , and this is the  $\sigma$ -algebra that encodes our information over all time.

#### The Martingale Convergence Theorems

If X is a sub-martingale relative to  $\mathfrak{F}$  then X has an *increasing property* of sorts:  $E(X_t | \mathscr{F}_s) \ge X_s$  for  $s, t \in T$  with  $s \le t$ . Similarly, if X is a super-martingale relative to  $\mathfrak{F}$  then X has a *decreasing property* of sorts, since the last inequality is reversed. Thus, there is hope that if this increasing or decreasing property is coupled with an appropriate boundedness property, then the submartingale or super-martingale might converge, in some sense, as  $t \to \infty$ . This is indeed the case, and is the subject of this section. The martingale convergence theorems, first formulated by Joseph Doob, are among the most important results in the theory of martingales. The *first martingale convergence theorem* states that if the expected absolute value is bounded in the time, then the martingale process converges with probability 1.

Suppose that  $X = \{X_t : t \in T\}$  is a sub-martingale or a super-martingale with respect to  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$  and that  $\mathbb{E}(|X_t|)$  is bounded in  $t \in T$ . Then there exists a random variable  $X_\infty$  that is measurable with respect to  $\mathscr{F}_\infty$  such that  $\mathbb{E}(|X_\infty|) < \infty$  and  $X_t \to X_\infty$  as  $t \to \infty$  with probability 1.

#### Proof

The proof is simple using the up-crossing inequality. Let  $T_t = \{s \in T : s \le t\}$  for  $t \in T$ . For  $a, b \in \mathbb{R}$  with a < b, let  $U_t(a, b)$  denote the number of up-crossings of the interval [a, b] by the process X on  $T_t$ , and let  $U_{\infty}(a, b)$  denote the number of up-crossings of [a, b] by X on T. Recall that  $U_t \uparrow U_{\infty}$  as  $t \to \infty$ . Suppose that  $\mathbb{E}(|X_t|) < c$  for  $t \in T$ , where  $c \in (0, \infty)$ . By the up-crossing inequality,

$$\mathbb{E}[U_t(a,b)] \le \frac{1}{b-a}[|a| + \mathbb{E}(|X_t|)] \le \frac{|a|+c}{b-a}, \quad n \in \mathbb{N}$$
(17.5.1)

By the monotone convergence theorem, it follows that

$$\mathbb{E}[U_{\infty}(a,b)] < \frac{|a|+c}{b-a} < \infty \tag{17.5.2}$$

Hence  $\mathbb{P}[U_{\infty}(a,b) < \infty] = 1$ . Therefore with probability 1,  $U_{\infty}(a,b) < \infty$  for every  $a, b \in \mathbb{Q}$  with a < b. By our characterization of convergence in terms of up-crossings, it follows that there exists a random variable  $X_{\infty}$  with values in  $\mathbb{R}^* = \mathbb{R} \cup \{-\infty, \infty\}$  such that with probability 1,  $X_t \to X_{\infty}$  as  $t \to \infty$ . Note that X is measurable with respect to  $\mathscr{F}_{\infty}$ . By Fatou's lemma,

$$\mathbb{E}(|X_{\infty}|) \leq \liminf_{t \to \infty} \mathbb{E}(|X_t|) < \infty$$
(17.5.3)

Hence  $\mathbb{P}(X_{\infty} \in \mathbb{R}) = 1$  .

The boundedness condition means that X is bounded (in norm) as a subset of the vector space  $\mathscr{L}_1$ . Here is a very simple, but useful corollary:

If  $X = \{X_t : t \in T\}$  is a nonnegative super-martingale with respect to  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$  then there exists a random variable  $X_{\infty}$ , measurable with respect to  $\mathscr{F}_{\infty}$ , such that  $X_t \to X_{\infty}$  with probability 1.

#### Proof

Since X is a nonnegative super-martinagle,  $\mathbb{E}(|X_t|) = \mathbb{E}(X_t) \le \mathbb{E}(X_0)$  for  $t \in T$ . Hence the previous martingale convergence theorem applies.

Of course, the corollary applies to a nonnegative martingale as a special case. For the second *martingale convergence theorem* you will need to review uniformly integrable variables. Recall also that for  $k \in [1, \infty)$ , the *k*-norm of a random variable *X* is

$$\|X\|_{k} = \left[\mathbb{E}\left(|X|^{k}\right)\right]^{1/k} \tag{17.5.4}$$

and  $\mathscr{L}_k$  is the normed vector space of all real-valued random variables for which this norm is finite. *Convergence in mean* refers to convergence in  $\mathscr{L}_1$  and more generally, *convergence in kth mean* refers to convergence in  $\mathscr{L}_k$ .

Suppose that X is a uniformly integrable and is a sub-martingale or super-martingale with respect to  $\mathfrak{F}$ . Then there exists a random variable  $X_{\infty}$ , measurable with respect to  $\mathscr{F}_{\infty}$  such that  $X_t \to X_{\infty}$  as  $t \to \infty$  with probability 1 and in mean. Moreover, if X is a martingale with respect to  $\mathfrak{F}$  then  $X_t = \mathbb{E}(X_{\infty} \mid \mathscr{F}_t)$  for  $t \in T$ .

Proof

Since  $X = \{X_t : t \in T\}$  is uniformly integrable,  $\mathbb{E}(|X_t|)$  is bounded in  $t \in T$ . Hence the by the first martingale convergence theorem, there exists  $X_{\infty}$  that is measurable with respect to  $\mathscr{F}_{\infty}$  such that  $\mathbb{E}(|X_{\infty}|) < \infty$  and  $X_t \to X_{\infty}$  as  $t \to \infty$  with probability 1. By the uniform integrability theorem, the convergence is also in mean, so that  $\mathbb{E}(|X_t - X|) \to 0$  as  $t \to \infty$ . Suppose now that X is a martingale with respect to  $\mathfrak{F}$  for fixed  $s \in T$  we know that  $\mathbb{E}(X_t | \mathscr{F}_s) \to \mathbb{E}(X_{\infty} | \mathscr{F}_s)$  as  $t \to \infty$  (with probability 1). But  $\mathbb{E}(X_t | \mathscr{F}_s) = X_s$  for  $t \ge s$  so it follows that  $X_s = \mathbb{E}(X_{\infty} | \mathscr{F}_s)$ .

As a simple corollary, recall that if  $||X_t||_k$  is bounded in  $t \in T$  for some  $k \in (1, \infty)$  then **X** is uniformly integrable, and hence the second martingale convergence theorem applies. But we can do better.

Suppose again that  $X = \{X_t : t \in T\}$  is a sub-martingale or super-martingale with respect to  $\mathfrak{F} = \{\mathscr{F}_t : t \in T\}$  and that  $\|X_t\|_k$  is bounded in  $t \in T$  for some  $k \in (1, \infty)$ . Then there exists a random variable  $X_{\infty} \in \mathscr{L}_k$  such that  $X_t \to X_{\infty}$  as  $t \to \infty$  in  $\mathscr{L}_k$ .

Proof

Suppose that  $||X_t||_k \le c$  for  $t \in T$  where  $c \in (0, \infty)$ . Since  $||X||_1 \le ||X||_k$ , we have  $\mathbb{E}(|X_t|)$  bounded in  $t \in T$  so the first martingale convergence theorem applies. Hence there exists  $X_{\infty}$ , measurable with respect to  $\mathscr{P}_{\infty}$ , such that  $X_t \to X_{\infty}$  as  $t \to \infty$  with probability 1. Equivalently, with probability 1,

$$|X_t - X_{\infty}|^k \to 0 \text{ as } t \to \infty$$
 (17.5.5)

Next, for  $t \in T$ , let  $T_t = \{s \in T : s \le t\}$  define  $W_t = \sup\{|X_s| : s \in T_t\}$ . by the norm version of the maximal inequality,

$$\|W_t\|_k \le \frac{k}{k-1} \|X_t\| \le \frac{kc}{k-1}, \quad t \in T$$
 (17.5.6)

If we let  $W_\infty = \sup\{|X_s|: s \in T\}$  , then by the montone convergence theorem

$$\|W_{\infty}\|_{k} = \lim_{t \to \infty} \|W_{t}\|_{k} \le \frac{ck}{k-1}$$
(17.5.7)

So  $W_{\infty} \in \mathscr{L}_k$ . But  $|X_{\infty}| \leq W_{\infty}$  so  $X_{\infty} \in \mathscr{L}_k$  also. Moreover,  $|X_t - X_{\infty}|^k \leq 2^k W_{\infty}^k$ , so applying the dominated convergence theorem to the first displayed equation above, we have  $\mathbb{E}(|X_t - X_{\infty}|^k) \to 0$  as  $t \to \infty$ .

#### **Example and Applications**

In this subsection, we consider a number of applications of the martingale convergence theorems. One indication of the importance of martingale theory is the fact that many of the classical theorems of probability have simple and elegant proofs when formulated in terms of martingales.

#### Simple Random Walk

Suppose now that that  $V = \{V_n : n \in \mathbb{N}\}$  is a sequence of independent random variables with  $\mathbb{P}(V_i = 1) = p$  and  $\mathbb{P}(V_i = -1) = 1 - p$  for  $i \in \mathbb{N}_+$ , where  $p \in (0, 1)$ . Let  $X = \{X_n : n \in \mathbb{N}\}$  be the partial sum process associated with V so that

$$X_n = \sum_{i=0}^n V_i, \quad n \in \mathbb{N}$$
(17.5.8)

Recall that X is the simple random walk with parameter p. From our study of Markov chains, we know that  $p > \frac{1}{2}$  then  $X_n \to \infty$  as  $n \to \infty$  and if  $p < \frac{1}{2}$  then  $X_n \to -\infty$  as  $n \to \infty$ . The chain is transient in these two cases. If  $p = \frac{1}{2}$ , the chain is (null) recurrent and so visits every state in  $\mathbb{N}$  infinitely often. In this case  $X_n$  does not converge as  $n \to \infty$ . But of course  $\mathbb{E}(X_n) = n(2p-1)$  for  $n \in \mathbb{N}$ , so the martingale convergence theorems do not apply.

#### Doob's Martingale

Recall that if *X* is a random variable with  $\mathbb{E}(|X|) < \infty$  and we *define*  $X_t = \mathbb{E}(X | \mathscr{F}_t)$  for  $t \in T$ , then  $X = \{X_t : t \in T\}$  is a martingale relative to  $\mathfrak{F}$  and is known as a Doob martingale, named for you know whom. So the second martingale convergence theorem states that every uniformly integrable martingale is a Doob martingale. Moreover, we know that the Doob martingale X constructed from X and  $\mathfrak{F}$  is uniformly integrable, so the second martingale convergence theorem applies. The last remaining question is the relationship between X and the limiting random variable  $X_{\infty}$ . The answer may come as no surprise.

Let  $X = \{X_t : t \in T\}$  be the Doob martingale constructed from X and  $\mathfrak{F}$ . Then  $X_t \to X_\infty$  as  $t \to \infty$  with probability 1 and in mean, where

$$X_{\infty} = \mathbb{E}(X \mid \mathscr{F}_{\infty}) \tag{17.5.9}$$

Of course if  $\mathscr{F}_{\infty} = \mathscr{F}$ , which is quite possible, then  $X_{\infty} = X$ . At the other extreme, if  $\mathscr{F}_t = \{\emptyset, \Omega\}$ , the trivial  $\sigma$ -algebra for all  $t \in T$ , then  $X_{\infty} = \mathbb{E}(X)$ , a constant.

#### Kolmogorov Zero-One Law

Suppose that  $\mathbf{X} = (X_n : n \in \mathbb{N}_+)$  is a sequence of random variables with values in a general state space  $(S, \mathscr{S})$ . Let  $\mathscr{G}_n = \sigma\{X_k : k \ge n\}$  for  $n \in \mathbb{N}_+$ , and let  $\mathscr{G}_\infty = \bigcap_{n=1}^\infty \mathscr{G}_n$ . So  $\mathscr{G}_\infty$  is the *tail*  $\sigma$ -algebra of  $\mathbf{X}$ , the collection of events that depend only on the terms of the sequence with arbitrarily large indices. For example, if the sequence is real-valued (or more generally takes values in a metric space), then the event that  $X_n$  has a limit as  $n \to \infty$  is a tail event. If  $B \in \mathscr{S}$ , then the event that  $X_n \in B$  for infinitely many  $n \in \mathbb{N}_+$  is another tail event. The *Kolmogorov zero-one law*, named for Andrei Kolmogorov, states that if  $\mathbf{X}$  is an independent sequence, then the tail events are essentially deterministic.

Suppose that X is a sequence of independent random variables. If  $A \in \mathscr{G}_{\infty}$  then  $\mathbb{P}(A) = 0$  or  $\mathbb{P}(A) = 1$ . Proof

Proor

Let  $\mathscr{F}_n = \sigma\{X_k : k \leq n\}$  for  $n \in \mathbb{N}_+$  so that  $\mathfrak{F} = \{\mathscr{F}_n : n \in \mathbb{N}_+\}$  is the natural filtration associated with X. As with our notation above, let  $\mathscr{F}_\infty = \sigma\left(\bigcup_{n \in \mathbb{N}_+} \mathscr{F}_n\right)$ . Now let  $A \in \mathscr{G}_\infty$  be a tail event. Then  $\{\mathbb{E}(\mathbf{1}_A \mid \mathscr{F}_n) : n \in \mathbb{N}_+\}$  is the Doob martingale associated with the indicator variable  $\mathbf{1}_A$  and  $\mathfrak{F}$ . By our results above,  $\mathbb{E}(\mathbf{1}_A \mid \mathscr{F}_n) \to \mathbb{E}(\mathbf{1}_A \mid \mathscr{F}_\infty)$  as  $n \to \infty$  with probability 1. But  $A \in \mathscr{F}_\infty$  so  $\mathbb{E}(\mathbf{1}_A \mid \mathscr{F}_\infty) = \mathbf{1}_A$ . On the other hand,  $A \in \mathscr{G}_{n+1}$  and the  $\sigma$ -algebras  $\mathscr{G}_{n+1}$  and  $\mathscr{F}_n$  are independent. Therefore  $\mathbb{E}(\mathbf{1}_A \mid \mathscr{F}_n) = \mathbb{P}(A)$  for each  $n \in \mathbb{N}_+$ . Thus  $\mathbb{P}(A) = \mathbf{1}_A$ .

Tail events and the Kolmogorov zero-one law were studied earlier in the section on measure in the chapter on probability spaces. A random variable that is measurable with respect to  $\mathscr{G}_{\infty}$  is a *tail random variable*. From the Kolmogorov zero-one law, a real-valued tail random variable for an independent sequence must be a constant (with probability 1).

#### **Branching Processes**

Recall the discussion of the simple *branching process* from the Introduction. The fundamental assumption is that the particles act independently, each with the same offspring distribution on  $\mathbb{N}$ . As before, we will let f denote the (discrete) probability density function of the number of offspring of a particle, m the mean of the distribution, and q the probability of extinction starting with a single particle. We assume that f(0) > 0 and f(0) + f(1) < 1 so that a particle has a positive probability of dying without children and a positive probability of producing more than 1 child.

The stochastic process of interest is  $X = \{X_n : n \in \mathbb{N}\}$  where  $X_n$  is the number of particles in the *n*th generation for  $n \in \mathbb{N}$ . Recall that X is a discrete-time Markov chain on  $\mathbb{N}$ . Since 0 is an absorbing state, and all positive states lead to 0, we know that the positive states are transient and so are visited only finitely often with probability 1. It follows that either  $X_n \to 0$  as  $n \to \infty$  (extinction) or  $X_n \to \infty$  as  $n \to \infty$  (explosion). We have quite a bit of information about which of these events will occur from our study of Markov chains, but the martingale convergence theorems give more information.

#### Extinction and explosion

1. If  $m \leq 1$  then q = 1 and extinction is certain.

2. If m > 1 then  $q \in (0, 1)$ . Either  $X_n \to 0$  as  $n \to \infty$  or  $X_n \to \infty$  as  $n \to \infty$  at an exponential rate.

Proof

The new information is the rate of divergence to  $\infty$  in (b). The other statements are from our study of discrete-time branching Markov chains. We showed in the Introduction that  $\{X_n/m^n : n \in \mathbb{N}\}$  is a martingale. Since this martingale is nonnegative, it has a limit as  $n \to \infty$ , and the limiting random variable takes values in  $\mathbb{R}$ . So if m > 1 and  $X_n \to \infty$  as  $n \to \infty$ , then the divergence to  $\infty$  must be at essentially the same rate as  $m^n$ .

#### The Beta-Bernoulli Process

Recall that the beta-Bernoulli process is constructed by randomizing the success parameter in a Bernoulli trials process with a beta distribution. Specifically, we start with a random variable P having the beta distribution with parameters  $a, b \in (0, \infty)$ . Next we have a sequence  $\mathbf{X} = (X_1, X_2, ...)$  of indicator variables with the property that  $\mathbf{X}$  is conditionally independent given  $P = p \in (0, 1)$  with  $\mathbb{P}(X_i = 1 | P = p) = p$  for  $i \in \mathbb{N}_+$ . Let  $\mathbf{Y} = \{Y_n : n \in \mathbb{N}\}$  denote the partial sum process associated with  $\mathbf{X}$ , so that once again,  $Y_n = \sum_{i=1}^n X_i$  for  $n \in \mathbb{N}$ . Next let  $M_n = Y_n/n$  for  $n \in \mathbb{N}_+$  so that  $M_n$  is the sample mean of  $(X_1, X_2, \ldots, X_n)$ . Finally let

$$Z_n = \frac{a + Y_n}{a + b + n}, \quad n \in \mathbb{N}$$
(17.5.10)

We showed in the Introduction that  $\mathbf{Z} = \{Z_n : n \in \mathbb{N}\}\$  is a martingale with respect to  $\mathbf{X}$ .

 $M_n \rightarrow P$  and  $Z_n \rightarrow P$  as  $n \rightarrow \infty$  with probability 1 and in mean.

Proof

We showed in the section on the beta-Bernoulli process that  $Z_n \to P$  as  $n \to \infty$  with probability 1. Note that  $0 \le Z_n \le 1$  for  $n \in \mathbb{N}$ , so the martingale Z is uniformly integrable. Hence the second martingale convergence theorem applies, and the convergence is in mean also.

This is a very nice result and is reminiscent of the fact that for the ordinary Bernoulli trials sequence with success parameter  $p \in (0, 1)$  we have the law of large numbers that  $M_n \to p$  as  $n \to \infty$  with probability 1 and in mean.

#### Pólya's Urn Process

Recall that in the simplest version of Pólya's urn process, we start with an urn containing a red and b green balls. At each discrete time step, we select a ball at random from the urn and then replace the ball and add c new balls of the same color to the urn. For the parameters, we need  $a, b \in \mathbb{N}_+$  and  $c \in \mathbb{N}$ . For  $i \in \mathbb{N}_+$ , let  $X_i$  denote the color of the ball selected on the *i*th draw, where 1 means red and 0 means green. For  $n \in \mathbb{N}$ , let  $Y_n = \sum_{i=1}^n X_i$ , so that  $\mathbf{Y} = \{Y_n : n \in \mathbb{N}\}$  is the partial sum process associated with  $\mathbf{X} = \{X_i : i \in \mathbb{N}_+\}$ . Since  $Y_n$  is the number of red balls in the urn at time  $n \in \mathbb{N}_+$ , the *average* number of balls at time n is  $M_n = Y_n/n$ . On the other hand, the total number of balls in the urn at time  $n \in \mathbb{N}$  is a + b + cn so the *proportion* of red balls in the urn at time n is

$$Z_n = \frac{a + cY_n}{a + b + cn} \tag{17.5.11}$$

We showed in the Introduction, that  $\mathbf{Z} = \{Z_n : n \in \mathbb{N}\}\$  is a martingale. Now we are interested in the limiting behavior of  $M_n$  and  $Z_n$  as  $n \to \infty$ . When c = 0, the answer is easy. In this case,  $Y_n$  has the binomial distribution with trial parameter n and success parameter a/(a+b), so by the law of large numbers,  $M_n \to a/(a+b)$  as  $n \to \infty$  with probability 1 and in mean. On the other hand,  $Z_n = a/(a+b)$  when c = 0. So the interesting case is when c > 0.

# LibreTexts

Suppose that  $c \in \mathbb{N}_+$ . Then there exists a random variable P such that  $M_n \to P$  and  $Z_n \to P$  as  $n \to \infty$  with probability 1 and in mean. Moreover, P has the beta distribution with left parameter a/c and right parameter b/c.

Proof

In our study of Póyla's urn process we showed that when  $c \in \mathbb{N}_+$  the process X is a beta-Bernoulli process with parameters a/c and b/c. So the result follows from our previous theorem.

#### Likelihood Ratio Tests

Recall the discussion of likelihood ratio tests in the Introduction. To review, suppose that  $(S, \mathscr{S}, \mu)$  is a general measure space, and that  $X = \{X_n : n \in \mathbb{N}\}$  is a sequence of independent, identically distributed random variables, taking values in S, and having a common probability density function with respect to  $\mu$ . The likelihood ratio test is a hypothesis test, where the null and alternative hypotheses are

- $H_0$ : the probability density function is  $g_0$ .
- $H_1$ : the probability density function is  $g_1$ .

We assume that  $g_0$  and  $g_1$  are positive on S. Also, it makes no sense for  $g_0$  and  $g_1$  to be the same, so we assume that  $g_0 \neq g_1$  on a set of positive measure. The test is based on the *likelihood ratio test statistic* 

$$L_n = \prod_{i=1}^n \frac{g_0(X_i)}{g_1(X_i)}, \quad n \in \mathbb{N}$$
 (17.5.12)

We showed that under the alternative hypothesis  $H_1$ ,  $L = \{L_n : n \in \mathbb{N}\}$  is a martingale with respect to X, known as the *likelihood ratio martingale*.

Under  $H_1$ ,  $L_n \to 0$  as  $n \to \infty$  with probability 1.

Proof

Assume that  $H_1$  is true. L is a nonnegative martingale, so the first martingale convergence theorem applies, and hence there exists a random variable  $L_{\infty}$  with values in  $[0, \infty)$  such that  $L_n \to L_{\infty}$  as  $n \to \infty$  with probability 1. Next note that

$$\ln(L_n) = \sum_{i=1}^n \ln\left[\frac{g_0(X_i)}{g_1(X_i)}\right]$$
(17.5.13)

The variables  $\ln[g_0(X_i)/g_1(X_i)]$  for  $i \in \mathbb{N}_+$  are also independent and identically distributed, so let m denote the common mean. The natural logarithm is concave and the martingale L has mean 1, so by Jensen's inequality,

$$m = \mathbb{E}\left(\ln\left[\frac{g_0(X)}{g_1(X)}\right]\right) < \ln\left(\mathbb{E}\left[\frac{g_0(X)}{g_1(X)}\right]\right) = \ln(1) = 0$$
(17.5.14)

Hence  $m \in [-\infty, 0)$ . By the strong law of large numbers,  $\frac{1}{n} \ln(L_n) \to m$  as  $n \to \infty$  with probability 1. Hence we must have  $\ln(L_n) \to -\infty$  as  $n \to \infty$  with probability 1. But by continuity,  $\ln(L_n) \to \ln(L_\infty)$  as  $n \to \infty$  with probability 1, so  $L_\infty = 0$  with probability 1.

This result is good news, statistically speaking. Small values of  $L_n$  are evidence in favor of  $H_1$ , so the decision rule is to reject  $H_0$  in favor of  $H_1$  if  $L_n \leq l$  for a chosen critical value  $l \in (0, \infty)$ . If  $H_1$  is true and the sample size n is sufficiently large, we will reject  $H_0$ . In the proof, note that  $\ln(L_n)$  must diverge to  $-\infty$  at least as fast as n diverges to  $\infty$ . Hence  $L_n \to 0$  as  $n \to \infty$  exponentially fast, at least. It also worth noting that L is a mean 1 martingale (under  $H_1$ ) so trivially  $\mathbb{E}(L_n) \to 1$  as  $n \to \infty$  even though  $L_n \to 0$  as  $n \to \infty$  with probability 1. So the likelihood ratio martingale is a good example of a sequence where the interchange of limit and expected value is not valid.

#### Partial Products

Suppose that  $X = \{X_n : n \in \mathbb{N}_+\}$  is an independent sequence of nonnegative random variables with  $\mathbb{E}(X_n) = 1$  for  $n \in \mathbb{N}_+$ . Let

$$Y_n = \prod_{i=1}^n X_i, \quad n \in \mathbb{N}$$
(17.5.15)

so that  $Y = \{Y_n : n \in \mathbb{N}\}$  is the partial product process associated with X. From our discussion of this process in the Introduction, we know that Y is a martingale with respect to X. Since Y is nonnegative, the second martingale convergence theorem applies, so there exists a random variable  $Y_\infty$  such that  $Y_n \to Y_\infty$  as  $n \to \infty$  with probability 1. What more can we say? The following result, known as the *Kakutani product martingale theorem*, is due to Shizuo Kakutani.

Let  $a_n = \mathbb{E}(\sqrt{X_n})$  for  $n \in \mathbb{N}_+$  and let  $A = \prod_{i=1}^{\infty} a_i$ . 1. If A > 0 then  $Y_n \to Y_\infty$  as  $n \to \infty$  in mean and  $\mathbb{E}(Y_\infty) = 1$ . 2. If A = 0 then  $Y_\infty = 0$  with probability 1.

Proof

Note that  $a_n > 0$  for  $n \in \mathbb{N}_+$  since  $X_n$  is nonnegative and  $\mathbb{P}(X_n > 0) > 0$ . Also, since  $x \mapsto \sqrt{x}$  is concave on  $(0, \infty)$  it follows from Jensen's inequality that

$$a_n = \mathbb{E}\left(\sqrt{X_n}\right) \le \sqrt{\mathbb{E}(X_n)} = 1$$
 (17.5.16)

Let  $A_n = \prod_{i=1}^n a_i$  for  $n \in \mathbb{N}$ . Since  $a_n \in (0, 1]$  for  $n \in \mathbb{N}_+$ , it follows that  $A_n \in (0, 1]$  for  $n \in \mathbb{N}$  and that  $A_n$  is decreasing in  $n \in \mathbb{N}$  with limit  $A = \prod_{i=1}^{\infty} a_i \in [0, 1]$ . Next let  $Z_n = \prod_{i=1}^n \sqrt{X_i}/a_i$  for  $n \in \mathbb{N}$ , so that  $\mathbf{Z} = \{Z_n : n \in \mathbb{N}\}$  is the partial product process associated with  $\{\sqrt{X_n}/a_n : n \in \mathbb{N}\}$ . Since  $\mathbb{E}(\sqrt{X_n}/a_n) = 1$  for  $n \in \mathbb{N}_+$ , the process  $\mathbf{Z}$  is also a nonnegative martingale, so there exists a random variable  $Z_\infty$  such that  $Z_n \to Z_\infty$  as  $n \to \infty$  with probability 1. Note that  $Z_n^2 = Y_n/A_n^2$ ,  $Y_n = A_n^2 Z_n^2$ , and  $Y_n \leq Z_n^2$  for  $n \in \mathbb{N}$ .

1. Suppose that A > 0. Since the martingale  $\boldsymbol{Y}$  has mean 1,

$$\mathbb{E}\left(Z_{n}^{2}\right) = \mathbb{E}(Y_{n}/A_{n}^{2}) = 1/A_{n}^{2} \le 1/A^{2} < \infty, \quad n \in \mathbb{N}$$
(17.5.17)

Let  $W_n = \max\{Z_k : k \in \{0, 1, ..., n\}\}$  for  $n \in \mathbb{N}$  so that  $W = \{W_n : n \in \mathbb{N}\}$  is the maximal process associated with Z. Also, let  $W_{\infty} = \sup\{Z_k : k \in \mathbb{N}\}$  and note that  $W_n \uparrow W_{\infty}$  as  $n \to \infty$ . By the  $\mathscr{L}_2$  maximal inequality,

$$\mathbb{E}(W_n^2) \le 4\mathbb{E}(Z_n^2) \le 4/A^2, \quad n \in \mathbb{N}$$
(17.5.18)

By the monotone convergence theorem,  $\mathbb{E}(W_{\infty}^2) = \lim_{n \to \infty} \mathbb{E}(W_n^2) \le 4/A^2$ . Since  $x \to x^2$  is strictly increasing on  $[0, \infty)$ ,  $W_{\infty}^2 = \sup\{Z_n^2 : n \in \mathbb{N}\}$  and so  $Y_n \le W_{\infty}^2$  for  $n \in \mathbb{N}$ . Since  $\mathbb{E}(W_{\infty}^2) < \infty$ , it follows that the martingale Y is uniformly integrable. Hence by the third martingale convergence theorem above,  $Y_n \to Y_{\infty}$  is mean. Since convergence in mean implies that the means converge,  $\mathbb{E}(Y_{\infty}) = \lim_{n \to \infty} \mathbb{E}(Y_n) = 1$ .

2. Suppose that A = 0. Then  $Y_n = A_n^2 Z_n^2 \to 0 \cdot Z_{\infty}^2 = 0$  as  $n \to \infty$  with probability 1. Note that in this case, the convergence is not in mean, and trivially  $\mathbb{E}(Y_{\infty}) = 0$ .

#### **Density Functions**

This discussion continues the one on density functions in the Introduction. To review, we start with our probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ and a filtration  $\mathfrak{F} = \{\mathscr{F}_n : n \in \mathbb{N}\}$  in discrete time. Recall again that  $\mathscr{F}_{\infty} = \sigma (\bigcup_{n=0}^{\infty} \mathscr{F}_n)$ . Suppose now that  $\mu$  is a finite measure on the sample space  $(\Omega, \mathscr{F})$ . For each  $n \in \mathbb{N} \cup \{\infty\}$ , the restriction of  $\mu$  to  $\mathscr{F}_n$  is a measure on  $(\Omega, \mathscr{F}_n)$  and similarly the restriction of  $\mathbb{P}$  to  $\mathscr{F}_n$  is a probability measure on  $(\Omega, \mathscr{F}_n)$ . To save notation and terminology, we will refer to these as  $\mu$  and  $\mathbb{P}$  on  $\mathscr{F}_n$ , respectively. Suppose now that  $\mu$  is absolutely continuous with respect to  $\mathbb{P}$  on  $\mathscr{F}_n$  for each  $n \in \mathbb{N}$ . By the Radon-Nikodym theorem,  $\mu$  has a density function (or Radon-Nikodym derivative)  $X_n : \Omega \to \mathbb{R}$  with respect to  $\mathbb{P}$  on  $\mathscr{F}_n$  for each  $n \in \mathbb{N}$ . The theorem and the derivative are named for Johann Radon and Otto Nikodym. In the Introduction we showed that  $X = \{X_n : n \in \mathbb{N}\}$  is a martingale with respect to  $\mathfrak{F}$ . Here is the convergence result:

There exists a random variable  $X_{\infty}$  such that  $X_n \to X_{\infty}$  as  $n \to \infty$  with probability 1.

1. If  $\mu$  is absolutely continuous with respect to  $\mathbb{P}$  on  $\mathscr{F}_{\infty}$  then  $X_{\infty}$  is a density function of  $\mu$  with respect to  $\mathbb{P}$  on  $\mathscr{F}_{\infty}$ .

2. If  $\mu$  and  $\mathbb{P}$  are mutually singular on  $\mathscr{F}_{\infty}$  then  $X_{\infty} = 0$  with probability 1.

Proof

Again, as shown in the Introduction, X is a martingale with respect to  $\mathfrak{F}$ . Moreover,  $\mathbb{E}(|X_n|) = \|\mu\|$  (the total variation of  $\mu$ ) for each  $n \in \mathbb{N}$ . Since  $\mu$  is a finite measure,  $\|\mu\| < \infty$  so the first martingale convergence theorem applies. Hence there exists a random variable  $X_{\infty}$ , measurable with respect to  $\mathscr{F}_{\infty}$ , such that  $X_n \to X_{\infty}$  as  $n \to \infty$ .

1. If  $\mu$  is absolutely continuous with respect to  $\mathbb{P}$  on  $\mathscr{F}_{\infty}$ , then  $\mu$  has a density function  $Y_{\infty}$  with respect to  $\mathbb{P}$  on  $\mathscr{F}_{\infty}$ . Our goal is to show that  $X_{\infty} = Y_{\infty}$  with probability 1. By definition,  $Y_{\infty}$  is measurable with respect to  $\mathscr{F}_{\infty}$  and

$$\int_{A} Y_{\infty} d\mathbb{P} = \mathbb{E}(Y_{\infty}; A) = \mu(A), \quad A \in \mathscr{F}_{\infty}$$
(17.5.19)

Suppose now that  $n \in \mathbb{N}$  and  $A \in \mathscr{F}_n$ . Then again by definition,  $\mathbb{E}(X_n; A) = \mu(A)$ . But  $A \in \mathscr{F}_\infty$  also, so  $\mathbb{E}(Y_\infty; A) = \mu(A)$ . So to summarize,  $X_n$  is  $\mathscr{F}_n$ -measurable and  $E(X_n : A) = \mathbb{E}(Y_\infty; A)$  for each  $A \in \mathscr{F}_n$ . By definition, this means that  $X_n = \mathbb{E}(Y_\infty \mid \mathscr{F}_n)$ , so X is the Doob martingale associated with  $Y_\infty$ . Letting  $n \to \infty$  and using the result above gives  $X_\infty = \mathbb{E}(Y_\infty \mid \mathscr{F}_\infty) = Y_\infty$  (with probability 1, of course).

2. Suppose that  $\mu$  and  $\mathbb{P}$  are mutually singular on  $\mathscr{F}_{\infty}$ . Assume first that  $\mu$  is a positive measure, so that  $X_n$  is nonnegative for  $n \in \mathbb{N} \cup \{\infty\}$ . By the definition of mutually singularity, there exists  $B \in \mathscr{F}_{\infty}$  such that  $\mu_{\infty}(B) = 0$  and  $\mathbb{P}_{\infty}(B^c) = 0$ , so that  $\mathbb{P}(B) = 1$ . Our goal is to show that  $\mathbb{E}(X_{\infty}; A) \leq \mu(A)$  for every  $A \in \mathscr{F}_{\infty}$ . Towards that end, let

$$\mathscr{M} = \{ A \in \mathscr{F}_{\infty} : \mathbb{E}(X_{\infty}; A) \le \mu(A) \}$$
(17.5.20)

Suppose that  $A \in \bigcup_{k=0}^{\infty} \mathscr{F}_k$ , so that  $A \in \mathscr{F}_k$  for some  $k \in \mathbb{N}$ . Then  $A \in \mathscr{F}_n$  for all  $n \ge k$  and therefore  $\mathbb{E}(X_n; A) = \mu(A)$  for all  $n \ge k$ . By Fatou's lemmas,

$$\mathbb{E}(X_{\infty}; A) \le \liminf_{n \to \infty} \mathbb{E}(X_n; A) \le \mu(A)$$
(17.5.21)

so  $A \in \mathscr{M}$ . Next, suppose that  $\{A_n : n \in \mathbb{N}\}$  is an increasing or decreasing sequence in  $\mathscr{M}$ , and let  $A_{\infty} = \lim_{n \to \infty} A_n$ (the union in the first case and the intersection in the second case). Then  $\mathbb{E}(X_{\infty}; A_n) \leq \mu(A_n)$  for each  $n \in \mathbb{N}$ . By the continuity theorems,  $\mathbb{E}(X_{\infty}; A_n) \to \mathbb{E}(X_{\infty}; A_{\infty})$  and  $\mu(A_n) \to \mu(A_{\infty})$  as  $n \to \infty$ . Therefore  $\mathbb{E}(X_{\infty}; A_{\infty}) \leq \mu(A_{\infty})$  and so  $A_{\infty} \in \mathscr{M}$ . It follows that  $\mathscr{M}$  is a monotone class. Since  $\mathscr{M}$  contains the algebra  $\bigcup_{n=0}^{\infty} \mathscr{F}_n$ , it then follows from the monotone class theorem that  $\mathscr{F}_{\infty} \subseteq \mathscr{M}$ . In particular  $B \in \mathscr{M}$ , so  $\mathbb{E}(X_{\infty}) = \mathbb{E}(X_{\infty}; B) \leq \mu(B) = 0$  and therefore  $X_{\infty} = 0$  with probability 1. If  $\mu$  is a general finite measure, then by the Jordan decomposition theorem,  $\mu$  can be written uniquely in the form  $\mu = \mu^+ - \mu^-$  where  $\mu^+$  and  $\mu^-$  are finite positive measures. Moreover,  $X_n^+$  is the density function of  $\mu^+$  on  $\mathscr{F}_n$  and  $X_n^-$  is the density function of  $\mu^-$  on  $\mathscr{F}_n$ . By the first part of the proof,  $X^+ = 0$ ,  $X^- = 0$ , and also X = 0, all with probability 1.

The martingale approach can be used to give a probabilistic proof of the Radon-Nikodym theorem, at least in certain cases. We start with a sample set  $\Omega$ . Suppose that  $\mathscr{A}_n = \{A_i^n : i \in I_n\}$  is a countable partition of  $\Omega$  for each  $n \in \mathbb{N}$ . Thus  $I_n$  is countable,  $A_i^n \cap A_j^n = \emptyset$  for distinct  $i, j \in I_n$ , and  $\bigcup_{i \in I_n} A_i^n = \Omega$ . Suppose also that  $\mathscr{A}_{n+1}$  refines  $\mathscr{A}_n$  for each  $n \in \mathbb{N}$  in the sense that  $A_i^n$  is a union of sets in  $\mathscr{A}_{n+1}$  for each  $i \in I_n$ . Let  $\mathscr{F}_n = \sigma(\mathscr{A}_n)$ . Thus  $\mathscr{F}_n$  is generated by a countable partition, and so the sets in  $\mathscr{F}_n$  are of the form  $\bigcup_{j \in J} A_j^n$  where  $J \subseteq I_n$ . Moreover, by the refinement property  $\mathscr{F}_n \subseteq \mathscr{F}_{n+1}$  for  $n \in \mathbb{N}$ , so that  $\mathfrak{F} = \{\mathscr{F}_n : n \in \mathbb{N}\}$  is a filtration. Let  $\mathscr{F} = \mathscr{F}_\infty = \sigma(\bigcup_{n=0}^\infty \mathscr{F}_n) = \sigma(\bigcup_{n=0}^\infty \mathscr{A}_n)$ , so that our sample space is  $(\Omega, \mathscr{F})$ . Finally, suppose that  $\mathbb{P}$  is a probability measure on  $(\Omega, \mathscr{F})$  with the property that  $\mathbb{P}(A_i^n) > 0$  for  $n \in \mathbb{N}$  and  $i \in I_n$ . We now have a probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ . Interesting probability spaces that occur in applications are of this form, so the setting is not as specialized as you might think.

Suppose now that  $\mu$  a finte measure on  $(\Omega, \mathscr{F})$ . From our assumptions, the only null set for  $\mathbb{P}$  on  $\mathscr{F}_n$  is  $\emptyset$ , so  $\mu$  is automatically absolutely continuous with respect to  $\mathbb{P}$  on  $\mathscr{F}_n$ . Moreover, for  $n \in \mathbb{N}$ , we can give the density function of  $\mu$  with respect to  $\mathbb{P}$  on  $\mathscr{F}_n$  explicitly:

The density function of  $\mu$  with respect to  $\mathbb{P}$  on  $\mathscr{F}_n$  is the random variable  $X_n$  whose value on  $A_i^n$  is  $\mu(A_i^n)/\mathbb{P}(A_i^n)$  for each  $i \in I_n$ . Equivalently,

$$X_n = \sum_{i \in I_n} \frac{\mu(A_i^n)}{\mathbb{P}(A_i^n)} \mathbf{1}(A_i^n)$$
(17.5.22)

Proof

We need to show that  $\mu(A) = \mathbb{E}(X_n; A)$  for each  $A \in \mathscr{F}_n$ . So suppose  $A = igcup_{j \in J} A_j^n$  where  $J \subseteq I_n$  . Then

$$\mathbb{E}(X_n; A) = \sum_{j \in J} \mathbb{E}(X_n; A_j^n) = \sum_{j \in J} \frac{\mu(A_j^n)}{\mathbb{P}(A_j^n)} \mathbb{P}(A_j^n) = \sum_{j \in J} \mu(A_j^n) = \mu(A)$$
(17.5.23)

By our theorem above, there exists a random variable X such that  $X_n \to X$  as  $n \to \infty$  with probability 1. If  $\mu$  is absolutely continuous with respect to  $\mathbb{P}$  on  $\mathscr{F}$ , then X is a density function of  $\mu$  with respect to  $\mathbb{P}$  on  $\mathscr{F}$ . The point is that we have given a more or less explicit construction of the density.

For a concrete example, consider  $\Omega = [0,1).$  For  $n \in \mathbb{N},$  let

$$\mathscr{A}_{n} = \left\{ \left[ \frac{j}{2^{n}}, \frac{j+1}{2^{n}} \right) : j \in \{0, 1, \dots, 2^{n} - 1\} \right\}$$
(17.5.24)

This is the partition of [0, 1) into  $2^n$  subintervals of equal length  $1/2^n$ , based on the *dyadic rationals* (or *binary rationals*) of rank n or less. Note that every interval in  $\mathscr{A}_n$  is the union of two adjacent intervals in  $\mathscr{A}_{n+1}$ , so the refinement property holds. Let  $\mathbb{P}$  be ordinary Lebesgue measure on [0, 1) so that  $\mathbb{P}(A_i^n) = 1/2^n$  for  $n \in \mathbb{N}$  and  $i \in \{0, 1, \ldots, 2^n - 1\}$ . As above, let  $\mathscr{F}_n = \sigma(\mathscr{A}_n)$  and  $\mathscr{F} = \sigma(\bigcup_{n=0}^{\infty} \mathscr{F}_n) = \sigma(\bigcup_{n=0}^{\infty} \mathscr{A}_n)$ . The dyadic rationals are dense in [0, 1), so  $\mathscr{F}$  is the ordinary Borel  $\sigma$ -algebra on [0, 1). Thus our probability space  $(\Omega, \mathscr{F}, \mathbb{P})$  is simply [0, 1) with the usual Euclidean structures. If  $\mu$  is a finite measure on  $([0, 1), \mathscr{F})$  then the density function of  $\mu$  on  $\mathscr{F}_n$  is the random variable  $X_n$  whose value on the interval  $[j/2^n, (j+1)/2^n)$  is  $2^n \mu [j/2^n, (j+1)/2^n)$ . If  $\mu$  is absolutely continuous with respect to  $\mathbb{P}$  on  $\mathscr{F}$  (so absolutely continuous in the usual sense), then a density function of  $\mu$  is  $X = \lim_{n \to \infty} X_n$ .

## 17.6: Backwards Martingales

#### **Basic Theory**

A *backwards martingale* is a stochastic process that satisfies the martingale property reversed in time, in a certain sense. In some ways, backward martingales are simpler than their forward counterparts, and in particular, satisfy a convergence theorem similar to the convergence theorem for ordinary martingales. The importance of backward martingales stems from their numerous applications. In particular, some of the fundamental theorems of classical probability can be formulated in terms of backward martingales.

#### Definitions

As usual, we start with a stochastic process  $\mathbf{Y} = \{Y_t : t \in T\}$  on an underlying probability space  $(\Omega, \mathscr{F}, \mathbb{P})$ , having state space  $\mathbb{R}$ , and where the index set T (representing time) is either  $\mathbb{N}$  (discrete time) or  $[0, \infty)$  (continuous time). So to review what all this means,  $\Omega$  is the sample space,  $\mathscr{F}$  the  $\sigma$ -algebra of events,  $\mathbb{P}$  the probability measure on  $(\Omega, \mathscr{F})$ , and  $Y_t$  is a random variable with values in  $\mathbb{R}$  for each  $t \in T$ . But at this point our formulation diverges. Suppose that  $\mathscr{G}_t$  is a sub  $\sigma$ -algebra of  $\mathscr{F}$  for each  $t \in T$ , and that  $\mathfrak{G} = \{\mathscr{G}_t : t \in T\}$  is *decreasing* so that if  $s, t \in T$  with  $s \leq t$  then  $\mathscr{G}_t \subseteq \mathscr{G}_s$ . Let  $\mathscr{G}_\infty = \bigcap_{t \in T} \mathscr{G}_t$ . We assume that  $Y_t$  is measurable with respect to  $\mathscr{G}_t$  and that  $\mathbb{E}(|Y_t|) < \infty$  for each  $t \in T$ .

The process  $\mathbf{Y} = \{Y_t : t \in T\}$  is a backwards martingale (or reversed martingale) with respect to  $\mathfrak{G} = \{\mathscr{G}_t : t \in T\}$  if  $\mathbb{E}(Y_s \mid \mathscr{G}_t) = Y_t$  for all  $s, t \in T$  with  $s \leq t$ .

A backwards martingale can be formulated as an ordinary martingale by using negative times as the indices. Let  $T^- = \{-t : t \in T\}$ , so that if  $T = \mathbb{N}$  (the discrete case) then  $T^-$  is the set of non-positive integers, and if  $T = [0, \infty)$  (the continuous case) then  $T^- = (-\infty, 0]$ . Recall also that the standard martingale definitions make sense for any totally ordered index set.

Suppose again that  $\boldsymbol{Y} = \{Y_t : t \in T\}$  is a backwards martingale with respect to  $\mathfrak{G} = \{\mathscr{G}_t : t \in T\}$ . Let  $X_t = Y_{-t}$  and  $\mathscr{F}_t = \mathscr{G}_{-t}$  for  $t \in T^-$ . Then  $\boldsymbol{X} = \{X_t : t \in T^-\}$  is a martingale with respect to  $\mathfrak{F} = \{\mathscr{F}_t : t \in T^-\}$ .

Proof

Since  $\mathfrak{G}$  is a decreasing family of sub  $\sigma$ -algebras of  $\mathscr{F}$ , the collection  $\mathfrak{F}$  is an increasing family of sub  $\sigma$ -algebras of  $\mathscr{F}$ , and hence is a filtration. Next,  $X_t = Y_{-t}$  is measurable with respect to  $\mathscr{G}_{-t} = \mathscr{F}_t$  for  $t \in T^-$ , so X is adapted to  $\mathfrak{F}$ . Finally, if  $s, t \in T^-$  with  $s \leq t$  then  $-t \leq -s$  so

$$\mathbb{E}(X_t \mid \mathscr{F}_s) = \mathbb{E}(Y_{-t} \mid \mathscr{G}_{-s}) = Y_{-s} = X_s$$
(17.6.1)

Most authors define backwards martingales with negative indices, as above, in the first place. There are good reasons for doing so, since some of the fundamental theorems of martingales apply immediately to backwards martingales. However, for the *applications* of backwards martingales, this notation is artificial and clunky, so for the most part, we will use our original definition. The next result is another way to view a backwards martingale as an ordinary martingale. This one preserves nonnegative time, but introduces a finite time horizon. For  $t \in T$ , let  $T_t = \{s \in T : s \leq t\}$ , a notation we have used often before.

Suppose again that  $\boldsymbol{Y} = \{Y_t : t \in T\}$  is a backwards martingale with respect to  $\mathfrak{G} = \{\mathscr{G}_t : t \in T\}$ . Fix  $t \in T$  and define  $X_s^t = Y_{t-s}$  and  $\mathscr{F}_s^t = \mathscr{G}_{t-s}$  for  $s \in T_t$ . Then  $\boldsymbol{X}^t = \{X_s^t : s \in T_t\}$  is a martingale relative to  $\mathfrak{F}^t = \{\mathscr{F}_s^t : s \in T_t\}$ .

#### Proof

The proof is essentially the same as for the previous result. Since  $\mathfrak{G}$  is a decreasing family of sub  $\sigma$ -algebras of  $\mathscr{F}$ , the collection  $\mathfrak{F}^t$  is an increasing family of sub  $\sigma$ -algebras of  $\mathscr{F}$ , and hence is a filtration. Next,  $X_s^t = Y_{t-s}$  is measurable with respect to  $\mathscr{G}_{t-s} = \mathscr{F}_s^t$  for  $s \in T_t$ , so  $\mathbf{X}^t$  is adapted to  $\mathfrak{F}^t$ . Finally, if  $r, s \in T_t$  with  $r \leq s$  then  $t-s \leq t-r$  so

$$\mathbb{E}(X_s^t \mid \mathscr{F}_r^t) = \mathbb{E}(Y_{t-s} \mid \mathscr{G}_{t-r}) = Y_{t-r} = X_r^t$$
(17.6.2)

#### **Properties**

Backwards martingales satisfy a simple and important property.

Suppose that  $Y = \{Y_t : t \in T\}$  is a backwards martingale with repsect to  $\mathfrak{G} = \{\mathscr{G}_t : t \in T\}$ . Then  $Y_t = \mathbb{E}(Y_0 \mid \mathscr{G}_t)$  for  $t \in T$  and hence Y is uniformly integrable.

Proof

The fact that  $Y_t = \mathbb{E}(Y_0 \mid \mathscr{G}_t)$  for  $t \in T$  follows directly from the definition of a backwards martingale. Since we have assumed that  $\mathbb{E}(|Y_0|) < \infty$ , it follows from a basic property that Y is uniformly integrable.

Here is the *Doob backwards martingale*, analogous to the ordinary Doob martingale, and of course named for Joseph Doob. In a sense, this is the converse to the previous result.

Suppose that *Y* is a random variable on our probability space  $(\Omega, \mathscr{F}, \mathbb{P})$  with  $\mathbb{E}(|Y|) < \infty$ , and that  $\mathfrak{G} = \{\mathscr{G}_t : t \in T\}$  is a decreasing family of sub  $\sigma$ -algebras of  $\mathscr{F}$ , as above. Let  $Y_t = \mathbb{E}(Y | \mathscr{G}_t)$  for  $t \in T$ . Then  $Y = \{Y_t : t \in T\}$  is a backwards martingale with respect to  $\mathfrak{G}$ .

Proof

By definition,  $Y_t = \mathbb{E}(Y \mid \mathscr{G}_t)$  is measurable with respect to  $\mathscr{G}_t$ . Also,

$$\mathbb{E}(|Y_t|) = \mathbb{E}[|\mathbb{E}(Y \mid \mathscr{G}_t)|] \le \mathbb{E}[\mathbb{E}(|Y| \mid \mathscr{G}_t)] = \mathbb{E}(|Y|) < \infty, \quad t \in T$$
(17.6.3)

Next, suppose that s,  $t \in T$  with  $s \leq t$ . Then  $\mathscr{G}_t \subseteq \mathscr{G}_s$  so by the tower property of conditional expected value,

$$\mathbb{E}(Y_s \mid \mathscr{G}_t) = \mathbb{E}[\mathbb{E}(Y \mid \mathscr{G}_s) \mid \mathscr{G}_t] = \mathbb{E}(Y \mid \mathscr{G}_t) = Y_t$$
(17.6.4)

The convergence theorems are the most important results for the applications of backwards martingales. Recall once again that for  $k \in [1, \infty)$ , the *k*-norm of a real-valued random variable *X* is

$$\|X\|_{k} = \left[\mathbb{E}\left(|X|^{k}\right)\right]^{1/k} \tag{17.6.5}$$

and the normed vector space  $\mathscr{L}_k$  consists of all X with  $||X||_k < \infty$ . Convergence in the space  $\mathscr{L}_1$  is also referred to as *convergence in mean*, and convergence in the space  $\mathscr{L}_2$  is referred to as *convergence in mean square*. Here is the primary *backwards martingale convergence theorem*:

Suppose again that  $Y = \{Y_t : t \in T\}$  is a backwards martingale with respect to  $\mathfrak{G} = \{\mathscr{G}_t : t \in T\}$ . Then there exists a random variable  $Y_\infty$  such that

1.  $Y_t \to Y_\infty$  as  $t \to \infty$  with probability 1. 2.  $Y_t \to Y_\infty$  as  $t \to \infty$  in mean. 3.  $Y_\infty = \mathbb{E}(Y_0 \mid \mathscr{G}_\infty)$ .

Proof

The proof is essentially the same as the ordinary martingale convergence theorem if we use the martingale constructed from  $\boldsymbol{Y}$  above. So, fix  $t \in T$  and let  $T_t = \{s \in T : s \leq t\}$ . Let  $X_s^t = Y_{t-s}$  and  $\mathscr{P}_s^t = \mathscr{G}_{t-s}$  for  $s \in T_t$ , so that  $\boldsymbol{X}^t = \{X_s^t : s \in T_t\}$  is a martingale relative to  $\mathfrak{F}^t = \{\mathscr{P}_s^t : s \in T_t\}$ . Now, for  $a, b \in \mathbb{R}$  with a < b, let  $U_t(a, b)$  denote the number of up-crossings of [a, b] by  $\boldsymbol{X}^t$  on  $T_t$ . Note that  $U_t(a, b)$  is also the number of *down-crossings* of [a, b] by  $\boldsymbol{Y}$  on  $T_t$ . By the up-crossing inequality applied to the martingale  $\boldsymbol{X}^t$ ,

$$\mathbb{E}[U_t(a,b)] \le \frac{1}{b-a} [\mathbb{E}(|X_t|) + |a|] = \frac{1}{b-a} [\mathbb{E}(|Y_0|) + |a|]$$
(17.6.6)

Now let  $U_{\infty}(a, b)$  denote the number of down-crossings of [a, b] by Y on all of T. Since  $U_t \uparrow U_{\infty}$  as  $t \to -\infty$  it follows from the monotone convergence theorem that

$$E[U_{\infty}(a,b)] \leq \frac{1}{b-a} \left[ \mathbb{E}(|Y_0|) + |a| \right]$$
(17.6.7)

Hence with probability 1,  $U_{\infty}(a, b) < \infty$  for every  $a, b \in \mathbb{Q}$  with a < b. By the characterization of convergence in terms of downcrossings (completely analogous to the one for up-crossings), there exists a random variable  $Y_{\infty}$  with values in  $\mathbb{R}^* = \mathbb{R} \cup \{-\infty, \infty\}$  such that  $Y_t \to Y_{\infty}$  as  $t \to \infty$ . By Fatou's lemma,

$$\mathbb{E}(|Y_{\infty}|) \leq \liminf_{t \to \infty} \mathbb{E}(|Y_t|) \leq \mathbb{E}(|Y_0|) < \infty$$
(17.6.8)

In particular,  $\mathbb{P}(Y_{\infty} \in \mathbb{R}) = 1$ . Since Y is uniformly integrable, and  $Y_{\infty} \in \mathscr{L}_1$ , it follows that  $Y_t \to Y_{\infty}$  as  $t \to \infty$  in  $\mathscr{L}_1$  also.

It remains to show that  $Y_{\infty} = \mathbb{E}(Y_0 \mid \mathscr{G}_{\infty})$ . Let  $A \in \mathscr{G}_{\infty}$ . Then  $A \in \mathscr{G}_t$  for every  $t \in T$ . Since  $Y_t = \mathbb{E}(Y_0 \mid \mathscr{G}_t)$  it follows by definition that  $\mathbb{E}(Y_t; A) = \mathbb{E}(Y_0; A)$  for every  $t \in T$ . Letting  $t \to \infty$  and using the dominated convergence theorem, gives  $\mathbb{E}(Y_{\infty}; A) = \mathbb{E}(Y_0; A)$ . Hence  $Y_{\infty} = \mathbb{E}(Y_0 \mid \mathscr{G}_{\infty})$ .

As a simple extension of the last result, if  $Y_0 \in \mathscr{L}_k$  for some  $k \in [1, \infty)$  then the convergence is in  $\mathscr{L}_k$  also.

Suppose again that  $\mathbf{Y} = \{Y_t : t \in T\}$  is a backwards martingale relative to  $\mathfrak{G} = \{\mathscr{G}_t : t \in T\}$ . If  $Y_0 \in \mathscr{L}_k$  for some  $k \in [1, \infty)$  then  $Y_t \to Y_\infty$  as  $t \to \infty$  in  $\mathscr{L}_k$ .

Proof

The previous result applies, of course, so we know that there exists a random variable  $Y_{\infty} \in \mathscr{L}_1$  such that  $Y_t \to Y_{\infty}$  as  $t \to \infty$  with probability 1 and in  $\mathscr{L}_1$ . The function  $x \mapsto |x|^k$  is convex on  $\mathbb{R}$  so by Jensen's inequality for conditional expected value,

$$\mathbb{E}(|Y_t|^k) = \mathbb{E}[|\mathbb{E}(Y_0 \mid \mathscr{G}_t)|^k] \le \mathbb{E}[\mathbb{E}(|Y_0|^k \mid \mathscr{G}_t] = \mathbb{E}(|Y_0|^k) < \infty$$
(17.6.9)

so  $Y_t \in \mathscr{L}_k$  for every  $t \in T$  . By Fatou's lemma,

$$\mathbb{E}(|Y_{\infty}|^{k}) \leq \liminf_{t \to \infty} \mathbb{E}(|Y_{t}|^{k}) \leq \mathbb{E}(|Y_{0}|^{k}) < \infty$$
(17.6.10)

so  $Y_{\infty} \in \mathscr{L}_k$  also. Next, since  $Y_t = \mathbb{E}(Y_0 \mid \mathscr{G}_t)$  and  $Y_{\infty}$  is measurable with respect to  $\mathscr{G}_t$ , we can use Jensen's inequality again to get

$$|Y_t - Y_{\infty}|^k = |\mathbb{E}(Y_0 - Y_{\infty} \mid \mathscr{G}_t)|^k \le \mathbb{E}(|Y_0 - Y_{\infty}|^k \mid \mathscr{G}_t)$$
(17.6.11)

It follows that the family of random variables  $\{|Y_t - Y_{\infty}|^k : t \in T\}$  is uniformly integrable, and hence  $\mathbb{E}(|Y_t - Y_{\infty}|^k) \to 0$  as  $t \to \infty$ .

#### Applications

#### The Strong Law of Large Numbers

The strong law of large numbers is one of the fundamental theorems of classical probability. Our previous proof required that the underlying distribution have finite variance. Here we present an elegant proof using backwards martingales that does not require this extra assumption. So, suppose that  $X = \{X_n : n \in \mathbb{N}_+\}$  is a sequence of independent, identically distributed random variables with common mean  $\mu \in \mathbb{R}$ . In statistical terms, X corresponds to *sampling* from the underlying distribution. Next let

$$Y_n = \sum_{i=1}^n X_i, \quad n \in \mathbb{N}$$
(17.6.12)

so that  $\mathbf{Y} = \{Y_n : n \in \mathbb{N}\}$  is the partial sum process associated with  $\mathbf{X}$ . Recall that the sequence  $\mathbf{Y}$  is also a discrete-time random walk. Finally, let  $M_n = Y_n/n$  for  $n \in \mathbb{N}_+$  so that  $\mathbf{M} = \{M_n : n \in \mathbb{N}_+\}$  is the sequence of *sample means*.

The law of large numbers

1.  $M_n o \mu$  as  $n o \infty$  with probability 1.

2.  $M_n o \mu$  as  $n o \infty$  in mean.

Proof

As usual, let  $(\Omega, \mathscr{F}, \mathbb{P})$  denote the underlying probability space. Also, equalities involving random variables (and particularly conditional expected values) are assumed to hold with probability 1. Now, for  $n \in \mathbb{N}$ , let

$$\mathscr{G}_n = \sigma\{Y_n, Y_{n+1}, Y_{n+2}, \ldots\} = \sigma\{Y_n, X_{n+1}, X_{n+2} \ldots\}$$
(17.6.13)

so that  $\mathfrak{G} = \{\mathscr{G}_n : n \in \mathbb{N}\}\$  is a decreasing family of sub  $\sigma$ -algebras of  $\mathscr{F}$ . The core of the proof is to show that M is a backwards martingale relative to  $\mathfrak{G}$ . Let  $n \in \mathbb{N}_+$ . Clearly  $M_n$  is measurable with respect to  $\mathscr{G}_n$ . By independence,  $\mathbb{E}(X_i | \mathscr{G}_n) = \mathbb{E}(X_i | Y_n)$  for  $i \in \{1, 2, ..., n\}$  By symmetry (the sequence X is exchangeable),  $\mathbb{E}(X_i | Y_n) = \mathbb{E}(X_j | Y_n)$  for  $i, j \in \{1, 2, ..., n\}$ . Hence for  $i \in \{1, 2, ..., n\}$ 

$$Y_n = \mathbb{E}(Y_n \mid \mathscr{G}_n) = \sum_{j=1}^n E(X_j \mid \mathscr{G}_n) = \sum_{j=1}^n \mathbb{E}(X_i \mid \mathscr{G}_n) = n\mathbb{E}(X_i \mid \mathscr{G}_n)$$
(17.6.14)

so that  $\mathbb{E}(X_i \mid \mathscr{G}_n) = Y_n / n = M_n \;\; ext{for each } i \in \{1, 2, \dots, n\}$ . Next,

$$\mathbb{E}(Y_n \mid \mathscr{G}_{n+1}) = \mathbb{E}(Y_{n+1} - X_{n+1} \mid \mathscr{G}_{n+1}) = Y_{n+1} - \mathbb{E}(X_{n+1} \mid \mathscr{G}_{n+1}) = Y_{n+1} - \frac{1}{n+1}Y_{n+1} = \frac{n}{n+1}Y_{n+1}$$
(17.6.15)

Dividing by n gives  $\mathbb{E}(M_n | \mathscr{G}_{n+1}) = M_{n+1}$  and hence M is a backwards martingale with respect to  $\mathfrak{G}$ . From the backwards martingale convergence theorem, there exists  $M_\infty$  such that  $M_n \to M_\infty$  as  $n \to \infty$  with probability 1 and in mean. Next, for  $n, k \in \mathbb{N}_+$  simple algebra gives

$$M_{n+k} = \frac{1}{n+k} \sum_{i=1}^{k} X_i + \frac{n}{n+k} \frac{1}{n} \sum_{i=k+1}^{k+n} X_i$$
(17.6.16)

Letting  $n \to \infty$  then shows that

$$M_{\infty} = \lim_{n \to \infty} \frac{1}{n} \sum_{i=k+1}^{k+n} X_i$$
(17.6.17)

for every  $k \in \mathbb{N}_+$ . Hence  $M_\infty$  is a tail random variable for the IID sequence X. From the Kolmogorov 0-1 law,  $M_\infty$  must be a constant. Finally, convergence in mean implies that the means converge, and since  $\mathbb{E}(M_n) = \mu$  for each n, it follows that  $M_\infty = \mu$ .

#### **Exchangeable Variables**

We start with a probability space  $(\Omega, \mathscr{F}, \mathbb{P})$  and another measurable space  $(S, \mathscr{S})$ . Suppose that  $\mathbf{X} = (X_1, X_2, \ldots)$  is a sequence of random variables each taking values in S. Recall that  $\mathbf{X}$  is *exchangeable* if for every  $n \in \mathbb{N}$ , every permutation of  $(X_1, X_2, \ldots, X_n)$  has the same distribution on  $(S^n, \mathscr{S}^n)$  (where  $\mathscr{S}^n$  is the *n*-fold product  $\sigma$ -algebra). Clearly if  $\mathbf{X}$  is a sequence of independent, identically distributed variables, then  $\mathbf{X}$  is exchangeable. Conversely, if  $\mathbf{X}$  is exchangeable then the variables are identically distributed (by definition), but are not necessarily independent. The most famous example of a sequence that is exchangeable but not independent is Pólya's urn process, named for George Pólya. On the other hand, *conditionally* independent and identically distributed sequences *are* exchangeable. Thus suppose that  $(T, \mathscr{T})$  is another measurable space and that  $\Theta$  is a random variable taking values in T.

If X is conditionally independent and identically distributed given  $\Theta$ , then X is exchangeable.

#### Proof

Implicit in the statement is that the variables in the sequence have a regular conditional distribution  $\mu_{\Theta}$  given  $\Theta$ . Then for every  $n \in \mathbb{N}_+$ , the conditional distribution of every permutation of  $(X_1, X_2, \ldots, X_n)$ , given  $\Theta$ , is  $\mu^n_{\Theta}$  on  $(S^n, \mathscr{S}^n)$ , where  $\mu^n_{\Theta}$  is the *n*-fold product measure. Unconditionally, the distribution of any permutation is  $B \mapsto \mathbb{E}[\mu^n_{\Theta}(B)]$  for  $B \in \mathscr{S}^n$ .

Often the setting of this theorem arises when we start with a sequence of independent, identically distributed random variables that are governed by a parametric distribution, and then randomize one of the parameters. In a sense, we can always think of the setting in this way: Imagine that  $\theta \in T$  is a parameter for a distribution on S. A special case is the beta-Bernoulli process, in which the success parameter p in sequence of Bernoulli trials is randomized with the beta distribution. On the other hand, Pólya's urn process is an example of an exchangeable sequence that does not at first seem to have anything to do with randomizing parameters. But in fact, we know that Pólya's urn process is a special case of the beta-Bernoulli process. This connection gives a hint of *de Finetti's theorem*, named for Bruno de Finetti, which we consider next. This theorem states any exchangeable sequence of indicator random variables corresponds to randomizing the success parameter in a sequence of Bernoulli trials.

**de Finetti's Theorem**. Suppose that  $X = (X_1, X_2, ...)$  is an exchangeable sequence of random variables, each taking values in  $\{0, 1\}$ . Then there exists a random variable P with values in [0, 1], such that given  $P = p \in [0, 1]$ , X is a sequence of Bernoulli trials with success parameter p.

Proof

As usual, we need some notation. First recall the falling power notation  $r^{(j)} = r(r-1)\cdots(r-j+1)$  for  $r \in \mathbb{R}$  and  $j \in \mathbb{N}$ . Next for  $n \in \mathbb{N}_+$  and  $k \in \{0, 1, \dots, n\}$ , let

$$B_k^n = \left\{ (x_1, x_2, \dots, x_n) \in \{0, 1\}^n : \sum_{i=0}^n x_i = k 
ight\}$$
 (17.6.18)

That is,  $B_{\mu}^{n}$  is the set of bit strings of length *n* with 1 occurring exactly *k* times. Of course,  $\#(B_{\mu}^{n}) = {n \choose k} = n^{(k)}/k!$ .

Suppose now that  $\mathbf{X} = (X_1, X_2, ...)$  is an exchangeable sequence of variables with values in  $\{0, 1\}$ . For  $n \in \mathbb{N}_+$  let  $Y_n = \sum_{i=1}^n X_i$  and  $M_n = Y_n/n$ . So  $\mathbf{Y} = \{Y_n : n \in \mathbb{N}_+\}$  is the partial sum process associated with  $\mathbf{X}$  and  $\mathbf{M} = \{M_n : n \in \mathbb{N}_+\}$  the sequence of sample means. Let  $\mathscr{G}_n = \sigma\{Y_n, Y_{n+1}, ...\}$  and  $\mathscr{G}_{\infty} = \bigcap_{n=0}^{\infty} \mathscr{G}_n$ . The family of  $\sigma$ -algebras  $\mathfrak{G} = \{\mathscr{G}_n : n \in \mathbb{N}_+\}$  is decreasing. The key to the proof is to find two backwards martingales and use the backwards martingale convergence theorem.

Let  $m \in \mathbb{N}_+$  and  $k \in \{0, 1, \dots, m\}$  The crucial insight is that by exchangeability, given  $Y_m = k$ , the random vector  $(X_1, X_2, \dots, X_m)$  is uniformly distributed on  $B_k^m$ . So if  $n \in \mathbb{N}_+$  and  $n \le m$ , the random vector  $(X_1, X_2, \dots, X_n)$ , again given  $Y_m = k$ , fits the hypergeometric model: a sample of size n chosen at random and without replacement from a population of m objects of which k are type 1 and m - k are type 0. Thus, if  $j \in \{0, 1, \dots, n\}$  and  $(x_1, x_2, \dots, x_n) \in B_j^n$  then

$$\mathbb{P}(X_1 = x_1, X_2 = x_2, \dots, X_n = x_n \mid Y_m = k) = rac{k^{(j)}(m-k)^{(n-j)}}{m^{(n)}}$$
 (17.6.19)

Equivalently,

$$\mathbb{P}(X_1 = x_1, X_2 = x_2, \dots, X_n = x_n \mid Y_m) = \frac{Y_m^{(j)}(m - Y_m)^{(n-j)}}{m^{(n)}}$$
(17.6.20)

Given  $Y_m$ , the variables  $(Y_{m+1}, Y_{m+2}, ...)$  give no additional information about the distribution of  $(X_1, X_2, ..., X_n)$  and hence

$$\mathbb{P}(X_1 = x_1, X_2 = x_2, \dots, X_n = x_n \mid \mathscr{G}_m) = \mathbb{E}[\mathbf{1}(X_1 = x_1, X_2 = x_2, \dots, X_n = x_n) \mid \mathscr{G}_n] = rac{Y_m^{(j)}(m - Y_m)^{(n-j)}}{m^{(n)}} \quad (17.6.21)$$

For fixed n, j, and  $(x_1, x_2, \ldots, x_n) \in B_j^n$ , the conditional expected value in the middle of the displayed equation, as a function of m, is a Doob backward martingale with respect to  $\mathfrak{G}$  and hence converges to  $\mathbb{P}(X_1 = x_1, X_2 = x_2, \ldots, X_n = x_n \mid \mathscr{G}_{\infty})$  as  $m \to \infty$ .

Next we show that M is a backwards martingale with respect to  $\mathfrak{G}$ . Trivially  $M_n$  is measurable with respect to  $\mathfrak{G}_n$  and  $\mathbb{E}(M_n) \leq 1$  for each  $n \in \mathbb{N}$ . Thus we need to show that  $\mathbb{E}(M_n | \mathfrak{G}_m) = M_m$  for  $m, n \in \mathbb{N}_+$  with  $n \leq m$ . From our previous work with  $(X_1, X_2, \ldots, X_n)$  we know that the conditional distribution of  $Y_n$  given  $Y_m = k$  is hypergeometric with parameters m, k, and n:

$$\mathbb{P}(Y_n = j \mid Y_m = k) = \binom{n}{j} \frac{k^{(j)}(m-k)^{(n-j)}}{m^{(n)}}, \quad j \in \{0, 1, \dots, n\}$$
(17.6.22)

Recall that the mean of the hypergeometric distribution is the sample size times the proportion of type 1 objects in the population. Thus,

$$\mathbb{E}(M_n \mid Y_m = k) = \frac{1}{n} \mathbb{E}(Y_n \mid Y_m = k) = \frac{1}{n} n \frac{k}{m} = \frac{k}{m}$$
(17.6.23)

Or equivalently,  $\mathbb{E}(M_n \mid Y_m) = Y_m/m = M_m$ . Once again, given  $Y_m$ , the variables  $Y_{m+1}, Y_{m+2}$  give no additional information and so  $\mathbb{E}(Y_n \mid \mathscr{G}_m) = Y_m$ . Hence M is a backwards martingale with respect to  $\mathfrak{G}$ . From the backwards martingale convergence theorem, there exists a random variable P such that  $M_n \to P$  as  $n \to \infty$  with probability 1.

It just remains to connect the dots. Suppose now that  $n \in \mathbb{N}_+$  and  $j \in \{0, 1, \dots, n\}$  and that  $m \in \mathbb{N}_+$  and  $k_m \in \{0, 1, \dots, m\}$ . From simple calculus, if n and j are fixed and  $k_m/m \to p \in [0, 1]$  as  $m \to \infty$  then

$$\frac{k_m^{(j)}(m-k_m)^{(n-j)}}{m^{(n)}} \to p^j(1-p)^{n-j} \text{ as } m \to \infty$$
(17.6.24)

(You may recall that this computation is used in the proof of the convergence of the hypergeometric distribution to the binomial.) Returning to the joint distribution, recall that if  $(x_1, x_2, ..., x_n) \in B_i^n$  then

$$\mathbb{P}(X_1 = x_1, X_2 = x_2, \dots, X_n = x_n \mid \mathscr{G}_m) = \frac{Y_m^{(j)}(m - Y_m)^{(n-j)}}{m^{(n)}}$$
(17.6.25)

Let  $m \to \infty$ . Since  $Y_m/m \to P$  as  $m \to \infty$  we get

$$\mathbb{P}(X_1 = x_1, X_2 = x_2, \dots, X_n = x_n \mid \mathscr{G}_{\infty}) = P^j (1 - P)^{n - j}$$
(17.6.26)

Random variable P is measurable with respect to  $\mathscr{G}_\infty$  so

$$\mathbb{P}(X_1 = x_1, X_2 = x_2, \dots, X_n = x_n \mid P) = P^j (1 - P)^{n - j} \text{ as } m \to \infty$$
(17.6.27)

Given  $P=p\in[0,1]$  ,  $oldsymbol{X}$  is a sequence of Bernoulli trials with success parameter p .

De Finetti's theorem has been extended to much more general sequences of exchangeable variables. Basically, if  $\mathbf{X} = (X_1, X_2, ...)$  is an exchangeable sequence of random variables, each taking values in a significantly nice measurable space  $(S, \mathscr{S})$  then there exists a random variable  $\Theta$  such that  $\mathbf{X}$  is independent and identically distributed given  $\Theta$ . In the proof, the result that  $M_n \to P$  as  $n \to \infty$  with probability 1, where  $M_n = \frac{1}{n} \sum_{i=1}^n X_i$ , is known as *de Finetti's strong law of large numbers*. De Finetti's theorem, and it's generalizations are important in Bayesian statistical inference. For an exchangeable sequence of random variables (our observations in a statistical experiment), there is a hidden, random parameter  $\Theta$ . Given  $\Theta = \theta$ , the variables are independent and identically distributed. We gain information about  $\Theta$  by imposing a *prior distribution* on  $\Theta$  and then updating this, based on our observations and using Baye's theorem, to a *posterior distribution*.

Stated more in terms of distributions, de Finetti's theorem states that the distribution of *n* distinct variables in the exchangeable sequence is a *mixture* of product measures. That is, if  $\mu_{\theta}$  is the distribution of a generic *X* on  $(S, \mathscr{S})$  given  $\Theta = \theta$ , and  $\nu$  is the distribution of  $\Theta$  on  $(T, \mathscr{T})$ , then the distribution of *n* of the variables on  $(S^n \mathscr{S}^n)$  is

$$B \mapsto \int_{T} \mu_{\theta}^{n}(B) \, d\nu(\theta) \tag{17.6.28}$$

## **CHAPTER OVERVIEW**

## 18: Brownian Motion

Brownian motion is a stochastic process of great theoretical importance, and as the basic building block of a variety of other processes, of great practical importance as well. In this chapter we study Brownian motion and a number of random processes that can be constructed from Brownian motion. We also study the Ito stochastic integral and the resulting calculus, as well as two remarkable representation theorems involving stochastic integrals.

## 18.1: Standard Brownian Motion

#### Basic Theory

#### History

In 1827, the botanist Robert Brown noticed that tiny particles from pollen, when suspended in water, exhibited continuous but very jittery and erratic motion. In his "miracle year" in 1905, Albert Einstein explained the behavior physically, showing that the particles were constantly being bombarded by the molecules of the water, and thus helping to firmly establish the atomic theory of matter. Brownian motion as a mathematical random process was first constructed in rigorous way by Norbert Wiener in a series of papers starting in 1918. For this reason, the Brownian motion process is also known as the *Wiener process*.

Run the two-dimensional Brownian motion simulation several times in single-step mode to get an idea of what Mr. Brown may have observed under his microscope.

Along with the Bernoulli trials process and the Poisson process, the Brownian motion process is of central importance in probability. Each of these processes is based on a set of idealized assumptions that lead to a rich mathematial theory. In each case also, the process is used as a building block for a number of related random processes that are of great importance in a variety of applications. In particular, Brownian motion and related processes are used in applications ranging from physics to statistics to economics.

#### Definition

A standard Brownian motion is a random process  $X = \{X_t : t \in [0, \infty)\}$  with state space  $\mathbb{R}$  that satisfies the following properties:

- 1.  $X_0 = 0$  (with probability 1).
- 2. *X* has stationary increments. That is, for *s*,  $t \in [0, \infty)$  with s < t, the distribution of  $X_t X_s$  is the same as the distribution of  $X_{t-s}$ .
- 3. *X* has independent increments. That is, for  $t_1, t_2, \ldots, t_n \in [0, \infty)$  with  $t_1 < t_2 < \cdots < t_n$ , the random variables
- $X_{t_1}, X_{t_2}-X_{t_1}, \ldots, X_{t_n}-X_{t_{n-1}}$  are independent.
- 4.  $X_t$  is normally distributed with mean 0 and variance t for each  $t \in (0, \infty)$ .
- 5. With probability 1,  $t \mapsto X_t$  is continuous on  $[0, \infty)$ .

To understand the assumptions physically, let's take them one at a time.

- 1. Suppose that we measure the position of a Brownian particle in one dimension, starting at an arbitrary time which we designate as t = 0, with the initial position designated as x = 0. Then this assumption is satisfied by convention. Indeed, occasionally, it's convenient to relax this assumption and allow  $X_0$  to have other values.
- 2. This is a statement of *time homogeneity*: the underlying dynamics (namely the jostling of the particle by the molecules of water) do not change over time, so the distribution of the displacement of the particle in a time interval [*s*, *t*] depends only on the length of the time interval.
- 3. This is an idealized assumption that would hold approximately if the time intervals are large compared to the tiny times between collisions of the particle with the molecules.
- 4. This is another idealized assumption based on the central limit theorem: the position of the particle at time *t* is the result of a very large number of collisions, each making a very small contribution. The fact that the mean is 0 is a statement of *spatial homogeneity*: the particle is no more or less likely to be jostled to the right than to the left. Next, recall that the assumptions of stationary, independent increments means that  $var(X_t) = \sigma^2 t$  for some positive constant  $\sigma^2$ . By a change in time scale, we can assume  $\sigma^2 = 1$ , although we will consider more general Brownian motions in the next section.
- 5. Finally, the continuity of the sample paths is an essential assumption, since we are modeling the position of a physical particle as a function of time.

Of course, the first question we should ask is whether there *exists* a stochastic process satisfying the definition. Fortunately, the answer is yes, although the proof is complicated.

There exists a probability space  $(\Omega, \mathscr{F}, \mathbb{P})$  and a stochastic process  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  on this probability space satisfying the assumptions in the definition.

Proof sketch

The assumptions in the definition lead to a consistent set of finite dimensional distributions (which are given below). Thus by Kolmogorov existence theorem, there exists a stochastic process  $U = \{U_t : t \in [0, \infty)\}$  that has these finite dimensional distributions. However, U does not have continuous sample paths, but we can construct from U an equivalent process that does have continuous sample paths.

First recall that a *binary rational* (or *dyadic rational*) in  $[0, \infty)$  is a number of the form  $k/2^n$  where  $k, n \in \mathbb{N}$ . Let  $\mathbb{D}_+$  denote the set of all binary rationals in  $[0, \infty)$ , and recall that  $\mathbb{D}_+$  is countable but also *dense* in  $[0, \infty)$  (that is, if  $t \in [0, \infty) \setminus \mathbb{D}_+$  then there exists  $t_n \in \mathbb{D}_+$  for  $n \in \mathbb{N}_+$  such that  $t_n \to t$  as  $n \to \infty$ ).

Now, for  $n \in \mathbb{N}_+$ , let  $X_n(t) = U_t$  if t is a binary rational of the form  $k/2^n$  for some  $k \in \mathbb{N}$ . If t is not such a binary rational, define  $X_n(t)$  by linear interpolation between the the closest binary rationals of this form on either side of t. Then  $X_n(t) \to U(t)$  as  $n \to \infty$  for every  $t \in \mathbb{D}_+$ , and with probability 1, the convergence is uniform on  $\mathbb{D}_+ \cap [0, T]$  for each T > 0. It then follows that U is continuous on  $\mathbb{D}_+$  with probability 1.

For the last step, let  $X_t = \lim_{s \to t, s \in \mathbb{D}_+} U_s$  for  $t \in [0, \infty)$ . The limit exists since U is continuous on  $\mathbb{D}_+$  with probability 1. The process  $X = \{X_t : t \in [0, \infty)\}$  is continuous on  $[0, \infty)$  with probability 1, and has the same finite dimensional distributions as U.

Run the simulation of the standard Brownian motion process a few times in single-step mode. Note the qualitative behavior of the sample paths. Run the simulation 1000 times and compare the empirical density function and moments of  $X_t$  to the true probability density function and moments.

#### Brownian Motion as a Limit of Random Walks

Clearly the underlying dynamics of the Brownian particle being knocked about by molecules suggests a random walk as a possible model, but with tiny time steps and tiny spatial jumps. Let  $\mathbf{X} = (X_0, X_1, X_2, ...)$  be the symmetric simple random walk. Thus,  $X_n = \sum_{i=1}^n U_i$  where  $\mathbf{U} = (U_1, U_2, ...)$  is a sequence of independent variables with  $\mathbb{P}(U_i = 1) = \mathbb{P}(U_i = -1) = \frac{1}{2}$  for each  $i \in \mathbb{N}_+$ . Recall that  $\mathbb{E}(X_n) = 0$  and  $\operatorname{var}(X_n) = n$  for  $n \in \mathbb{N}$ . Also, since  $\mathbf{X}$  is the partial sum process associated with an IID sequence,  $\mathbf{X}$  has stationary, independent increments (but of course in discrete time). Finally, recall that by the central limit theorem,  $X_n / \sqrt{n}$  converges to the standard normal distribution as  $n \to \infty$ . Now, for  $h, d \in (0, \infty)$  the continuous time process

$$m{X}_{h,d} = \left\{ dX_{|t/h|} : t \in [0,\infty) 
ight\}$$
(18.1.1)

is a jump process with jumps at  $\{0, h, 2h, \ldots\}$  and with jumps of size  $\pm d$ . Basically we would like to let  $h \downarrow 0$  and  $d \downarrow 0$ , but this cannot be done arbitrarily. Note that  $\mathbb{E}[X_{h,d}(t)] = 0$  but var  $[X_{h,d}(t)] = d^2 \lfloor t/h \rfloor$ . Thus, by the central limit theorem, if we take  $d = \sqrt{h}$  then the distribution of  $X_{h,d}(t)$  will converge to the normal distribution with mean 0 and variance t as  $h \downarrow 0$ . More generally, we might hope that all of requirements in the definition are satisfied by the limiting process, and if so, we have a standard Brownian motion.

Run the simulation of the random walk process for increasing values of n. In particular, run the simulation several times with n = 100. Compare the qualitative behavior with the standard Brownian motion process. Note that the scaling of the random walk in time and space is effectively accomplished by scaling the horizontal and vertical axes in the graph window.

#### **Finite Dimensional Distributions**

Let  $X = \{X_t : t \in [0, \infty)\}$  be a standard Brownian motion. It follows from part (d) of the definition that  $X_t$  has probability density function  $f_t$  given by

$$f_t(x) = rac{1}{\sqrt{2\pi t}} \expigg(-rac{x^2}{2t}igg), \quad x \in \mathbb{R}$$
 $(18.1.2)$ 

This family of density functions determines the finite dimensional distributions of X.

If 
$$t_1, t_2, \ldots, t_n \in (0, \infty)$$
 with  $0 < t_1 < t_2 \cdots < t_n$  then  $(X_{t_1}, X_{t_2}, \ldots, X_{t_n})$  has probability density function  $f_{t_1, t_2, \ldots, t_n}$  given by

$$f_{t_1,t_2,\ldots,t_n}(x_1,x_2,\ldots,x_n) = f_{t_1}(x_1)f_{t_2-t_1}(x_2-x_1)\cdots f_{t_n-t_{n-1}}(x_n-x_{n-1}), \quad (x_1,x_2,\ldots,x_n) \in \mathbb{R}^n$$

$$(18.1.3)$$

Proof

This follows because  $\boldsymbol{X}$  has stationary, independent increments.

X is a Gaussian process with mean function mean function m(t) = 0 for  $t \in [0, \infty)$  and covariance function  $c(s, t) = \min\{s, t\}$  for  $s, t \in [0, \infty)$ .

Proof

The fact that X is a Gaussian process follows because  $X_t$  is normally distributed for each  $t \in T$  and X has stationary, independent increments. The mean function is 0 by assumption. For the covariance function, suppose  $s, t \in [0, \infty)$  with  $s \leq t$ . Since  $X_s$  and  $X_t - X_s$  are independent, we have

$$cov(X_s, X_t) = cov[X_s, X_s + (X_t - X_s)] = var(X_s) + 0 = s$$
(18.1.4)

Recall that for a Gaussian process, the finite dimensional (multivariate normal) distributions are completely determined by the mean function m and the covariance function c. Thus, it follows that a standard Brownian motion is characterized as a continuous Gaussian process with the mean and covariance functions in the last theorem. Note also that

$$\operatorname{cor}(X_s, X_t) = \frac{\min\{s, t\}}{\sqrt{st}} = \sqrt{\frac{\min\{s, t\}}{\max\{s, t\}}}, \quad (s, t) \in [0, \infty)^2$$
(18.1.5)

We can also give the higher moments and the moment generating function for  $X_t$ .

For  $n \in \mathbb{N}$  and  $t \in [0, \infty)$ ,

1. 
$$\mathbb{E}(X_t^{2n}) = 1 \cdot 3 \cdots (2n-1)t^n = (2n)!t^n/(n!2^n)$$
  
2.  $\mathbb{E}(X_t^{2n+1}) = 0$ 

Proof

These moments follow from standard results, since  $X_t$  is normally distributed with mean 0 and variance t.

For  $t \in [0, \infty)$ ,  $X_t$  has moment generating function given by

$$\mathbb{E}\left(e^{uX_t}\right) = e^{tu/2}, \quad u \in \mathbb{R} \tag{18.1.6}$$

Proof

Again, this is a standard result for the normal distribution.

#### Simple Transformations

There are several simple transformations that preserve standard Brownian motion and will give us insight into some of its properties. As usual, our starting place is a standard Brownian motion  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$ . Our first result is that reflecting the paths of  $\mathbf{X}$  in the line x = 0 gives another standard Brownian motion

Let  $Y_t = -X_t$  for  $t \ge 0$ . Then  $oldsymbol{Y} = \{Y_t : t \ge 0\}$  is also a standard Brownian motion.

Proof

Clearly the new process is still a Gaussian process, with mean function  $\mathbb{E}(-X_t) = -\mathbb{E}(X_t) = 0$  for  $t \in [0, \infty)$  and covariance function  $\operatorname{cov}(-X_s, -X_t) = \operatorname{cov}(X_s, X_t) = \min\{s, t\}$  for  $(s, t) \in [0, \infty)^2$ . Finally, since  $\boldsymbol{X}$  is continuous, so is  $\boldsymbol{Y}$ .

Our next result is related to the Markov property, which we explore in more detail below. If we "restart" Brownian motion at a fixed time s, and shift the origin to  $X_s$ , then we have another standard Brownian motion. This means that Brownian motion is both *temporally and spatially homogeneous*.

Fix  $s \in [0,\infty)$  and define  $Y_t = X_{s+t} - X_s$  for  $t \ge 0$ . Then  $\boldsymbol{Y} = \{Y_t : t \in [0,\infty)\}$  is also a standard Brownian motion.

Proof

Since *X* has stationary, independent increments, the process *Y* is equivalent in distribution to *X*. Clearly also *Y* is continuous since *X* is.

Our next result is a simple time reversal, but to state this result, we need to restrict the time parameter to a bounded interval of the form [0, T] where T > 0. The upper endpoint T is sometimes referred to as a *finite time horizon*. Note that  $\{X_t : t \in [0, T]\}$  still satisfies the definition, but with the time parameters restricted to [0, T].

Define 
$$Y_t = X_{T-t} - X_T$$
 for  $0 \le t \le T$ . Then  $Y = \{Y_t : t \in [0, T]\}$  is also a standard Brownian motion on  $[0, T]$ .

Proof

 $\boldsymbol{Y}$  is a Gaussian process, since a finite, linear combination of variables from this process reduces to a finite, linear combination of variables from  $\boldsymbol{X}$ . Next,  $\mathbb{E}(Y_t) = \mathbb{E}(X_{T-t}) - \mathbb{E}(X_T) = 0$  . Next, if  $s, t \in [0, T]$  with  $s \leq t$  then

$$\begin{aligned} & \operatorname{cov}(Y_s,Y_t) &= \operatorname{cov}(X_{T-s} - X_T, X_{T-t} - X_t) = \operatorname{cov}(X_{T-s}, X_{T-t}) - \operatorname{cov}(X_{T-s}, X_T) - \operatorname{cov}(X_T, X_{T-t}) + \operatorname{cov}(X_T, X_t) & (18.1.7) \\ &= (T-t) - (T-s) - (T-t) + T = s \end{aligned}$$

Finally,  $t \mapsto Y_t$  is continuous on [0, T] with probability 1, since  $t \mapsto X_t$  is continuous on [0, T] with probability 1.

Our next transformation involves scaling **X** both temporally and spatially, and is known as *self-similarity*.

Let a > 0 and define  $Y_t = \frac{1}{a} X_{a^2 t}$  for  $t \ge 0$ . Then  $\boldsymbol{Y} = \{Y_t : t \in [0, \infty)\}$  is also a standard Brownian motion.

Proof

Once again,  $\boldsymbol{Y}$  is a Gaussian process, since finite, linear combinations of variables in  $\boldsymbol{Y}$  reduce to finite, linear combinations of variables in  $\boldsymbol{X}$ . Next,  $\mathbb{E}(Y_t) = a\mathbb{E}(X_{a^2t}) = 0$  for t > 0, and for s, t > 0 with s < t,

$$\operatorname{cov}(Y_s, Y_t) = \operatorname{cov}\left(\frac{1}{a}X_{a^2s}, \frac{1}{a}X_{a^2t}\right) = \frac{1}{a^2}\operatorname{cov}\left(X_{a^2s}, X_{a^2t}\right) = \frac{1}{a^2}a^2s = s \tag{18.1.9}$$

Finally  $\boldsymbol{Y}$  is a continuous process since  $\boldsymbol{X}$  is continuous.

Note that the graph of Y can be obtained from the graph of X by scaling the time axis t by a factor of  $a^2$  and scaling the spatial axis x by a factor of a. The fact that the temporal scale factor must be the square of the spatial scale factor is clearly related to Brownian motion as the limit of random walks. Note also that this transformation amounts to "zooming in or out" of the graph of X and hence Brownian motion has a self-similar, fractal quality, since the graph is unchanged by this transformation. This also suggests that, although continuous,  $t \mapsto X_t$  is highly irregular. We consider this in the next subsection.

Our final transformation is referred to as time inversion.

Let  $Y_0 = 0$  and  $Y_t = tX_{1/t}$  for t > 0. Then  $Y = \{Y_t : t \in [0, \infty)\}$  is also a standard Brownian motion.

Proof

Clearly  $\boldsymbol{Y}$  is a Gaussian process, since finite, linear combinations of variables in  $\boldsymbol{Y}$  reduce to finite, linear combinations of variables in  $\boldsymbol{X}$ . Next,  $\mathbb{E}(Y_t) = t\mathbb{E}(X_{1/t}) = 0$  for t > 0, and for s, t > 0 with s < t,

$$\operatorname{cov}(Y_{s}, Y_{t}) = \operatorname{cov}(sX_{1/s}, tX_{1/t}) = st \operatorname{cov}(X_{1/s}, X_{1/t}) = st \frac{1}{t} = s$$
(18.1.10)

Since  $t \mapsto X_t$  is continuous on  $[0, \infty)$  with probability 1,  $t \mapsto Y_t$  is continuous on  $(0, \infty)$  with probability 1. Thus, all that remains is to show continuity at t = 0. Thus we need to show that with probability 1,  $tX_{1/t} \to 0$  as  $t \downarrow 0$ . or equivalently,  $X_s/s \to 0$  as  $s \uparrow \infty$ . But this last statement holds by the law of the iterated logarithm, given below.

#### Irregularity

The defining properties suggest that standard Brownian motion  $X = \{X_t : t \in [0, \infty)\}$  cannot be a smooth, differentiable function. Consider the usual difference quotient at t,

$$\frac{X_{t+h} - X_t}{h} \tag{18.1.11}$$

By the stationary increments property, if h > 0, the numerator has the same distribution as  $X_h$ , while if h < 0, the numerator has the same distribution as  $-X_{-h}$ , which in turn has the same distribution as  $X_{-h}$ . So, in both cases, the difference quotient has the same distribution as  $X_{|h|}/h$ , and this variable has the normal distribution with mean 0 and variance  $|h|/h^2 = 1/|h|$ . So the variance of the difference quotient diverges to  $\infty$  as  $h \to 0$ , and hence the difference quotient does not even converge in distribution, the weakest form of convergence.

The temporal-spatial transformation above also suggests that Brownian motion cannot be differentiable. The intuitive meaning of *differentiable* at t is that the function is *locally linear* at t—as we zoon in, the graph near t begins to look like a line (whose slope, of course, is the derivative). But as we zoon in on Brownian motion, (in the sense of the transformation), it always looks the same, and in particular, just as jagged. More formally, if X is differentiable at t, then so is the transformed process Y, and the chain rule gives  $Y'(t) = aX'(a^2t)$ . But Y is also a standard Brownian motion for every a > 0, so something is clearly wrong. While not rigorous, these examples are motivation for the following theorem:

With probability 1, **X** is nowhere differentiable on  $[0, \infty)$ .

Run the simulation of the standard Brownian motion process. Note the continuity but very jagged quality of the sample paths. Of course, the simulation cannot really capture Brownian motion with complete fidelity.

The following theorems gives a more precise measure of the irregularity of standard Brownian motion.

Standard Brownian motion X has Hölder exponent  $\frac{1}{2}$ . That is, X is Hölder continuous with exponent  $\alpha$  for every  $\alpha < \frac{1}{2}$ , but is not Hölder continuous with exponent  $\alpha$  for any  $\alpha > \frac{1}{2}$ .

In particular, *X* is not Lipschitz continuous, and this shows again that it is not differentiable. The following result states that in terms of Hausdorff dimension, the graph of standard Brownian motion lies midway between a simple curve (dimension 1) and the plane (dimension 2).

The graph of standard Brownian motion has Hausdorff dimension  $\frac{3}{2}$ .

Yet another indication of the irregularity of Brownian motion is that it has infinite total variation on any interval of positive length.

Suppose that  $a, \, b \in \mathbb{R}$  with a < b . Then the total variation of  $oldsymbol{X}$  on [a,b] is  $\infty$ .

#### The Markov Property and Stopping Times

As usual, we start with a standard Brownian motion  $X = \{X_t : t \in [0, \infty)\}$ . Recall that a Markov process has the property that the future is independent of the past, given the present state. Because of the stationary, independent increments property, Brownian motion has the property. As a minor note, to view X as a Markov process, we sometimes need to relax Assumption 1 and let  $X_0$  have an arbitrary value in  $\mathbb{R}$ . Let  $\mathscr{F}_t = \sigma\{X_s : 0 \le s \le t\}$ , the sigma-algebra generated by the process up to time  $t \in [0, \infty)$ . The family of  $\sigma$ -algebras  $\mathfrak{F} = \{\mathscr{F}_t : t \in [0, \infty)\}$  is known as a filtration.

Standard Brownian motion is a time-homogeneous Markov process with transition probability density p given by

$$p_t(x,y) = f_t(y-x) = rac{1}{\sqrt{2\pi t}} \expigg[-rac{(y-x)^2}{2t}igg], \quad t \in (0,\infty); \; x,\, y \in \mathbb{R}$$
(18.1.12)

Proof

Fix  $s \in [0, \infty)$ . The theorem follows from the fact that the process  $\{X_{s+t} - X_s : t \in [0, \infty)\}$  is another standard Brownian motion, as shown above, and is independent of  $\mathscr{F}_s$ .

The transiton density *p* satisfies the following *diffusion equations*. The first is known as the *forward equation* and the second as the *backward equation*.

$$\frac{\partial}{\partial t}p_t(x,y) = \frac{1}{2}\frac{\partial^2}{\partial y^2}p_t(x,y)$$
(18.1.13)

$$\frac{\partial}{\partial t}p_t(x,y) = \frac{1}{2}\frac{\partial^2}{\partial x^2}p_t(x,y)$$
(18.1.14)

Proof

These results follows from standard calculus.

The diffusion equations are so named, because the spatial derivative in the first equation is with respect to y, the state *forward* at time t, while the spatial derivative in the second equation is with respect to x, the state *backward* at time 0.

Recall that a random time  $\tau$  taking values in  $[0, \infty]$  is a *stopping time* with respect to the process  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  if  $\{\tau \leq t\} \in \mathscr{F}_t$  for every  $t \in [0, \infty)$ . Informally, we can determine whether or not  $\tau \leq t$  by observing the process up to time t. An important special case is the first time that our Brownian motion hits a specified state. Thus, for  $x \in \mathbb{R}$  let  $\tau_x = \inf\{t \in [0, \infty) : X_t = x\}$ . The random time  $\tau_x$  is a stopping time.

For a stopping time  $\tau$ , we need the  $\sigma$ -algebra of events that can be defined in terms of the process up to the random time  $\tau$ , analogous to  $\mathscr{F}_t$ , the  $\sigma$ -algebra of events that can be defined in terms of the process up to a fixed time t. The appropriate definition is

$$\mathscr{F}_{\tau} = \{ B \in \mathscr{F} : B \cap \{ \tau \le t \} \in \mathscr{F}_t \text{ for all } t \ge 0 \}$$

$$(18.1.15)$$

See the section on Filtrations and Stopping Times for more information on filtrations, stopping times, and the  $\sigma$ -algebra associated with a stopping time.

The *strong Markov property* is the Markov property generalized to stopping times. Standard Brownian motion X is also a strong Markov process. The best way to say this is by a generalization of the temporal and spatial homogeneity result above.

Suppose that  $\tau$  is a stopping time and define  $Y_t = X_{\tau+t} - X_{\tau}$  for  $t \in [0, \infty)$ . Then  $\mathbf{Y} = \{Y_t : t \in [0, \infty)\}$  is a standard Brownian motion and is independent of  $\mathscr{F}_{\tau}$ .

#### The Reflection Principle

Many interesting properties of Brownian motion can be obtained from a clever idea known as the *reflection principle*. As usual, we start with a standard Brownian motion  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$ . Let  $\tau$  be a stopping time for  $\mathbf{X}$ . Define

$$W_t = \begin{cases} X_t, & 0 \le t < \tau \\ 2X_\tau - X_t, & \tau \le t < \infty \end{cases}$$
(18.1.16)

Thus, the graph of  $W = \{W_t : t \in [0, \infty)\}$  can be obtained from the graph of X by reflecting in the line  $x = X_{\tau}$  after time  $\tau$ . In particular, if the stopping time  $\tau$  is  $\tau_a$ , the first time that the process hits a specified state a > 0, then the graph of W is obtained from the graph of X by reflecting in the line x = a after time  $\tau_a$ .

Open the simulation of reflecting Brownian motion. This app shows the process W corresponding to the stopping time  $\tau_a$ , the time of first visit to a positive state a. Run the simulation in single step mode until you see the reflected process several times. Make sure that you understand how the process W works.

The reflected process  $oldsymbol{W} = \{W_t : t \in [0,\infty)\}$  is also a standard Brownian motion.

Run the simulation of the reflected Brownian motion process 1000 times. Compaure the empirical density function and moments of  $W_t$  to the true probability density function and moments.

#### Martingales

As usual, let  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  be a standard Brownian motion, and let  $\mathscr{F}_t = \sigma\{X_s : 0 \le s \le t\}$  for  $t \in [0, \infty)$ , so that  $\mathfrak{F} = \{\mathscr{F}_t : t \in [0, \infty)\}$  is the natural filtration for  $\mathbf{X}$ . There are several important martingales associated with  $\mathbf{X}$ . We will study a couple of them in this section, and others in subsequent sections. Our first result is that  $\mathbf{X}$  itself is a martingale, simply by virtue of having stationary, independent increments and 0 mean.

 $oldsymbol{X}$  is a martingale with respect to  $\mathfrak{F}.$ 

Proof

Again, this is true of any process with stationary, independent increments and 0 mean, but we give the proof anyway, for completeness. Let  $s, t \in [0, \infty)$  with s < t. Since  $X_s$  is measurable with respect to  $\mathscr{F}_s$  and  $X_t - X_s$  is independent of  $\mathscr{F}_s$  we have

$$\mathbb{E}\left(X_t \mid \mathscr{F}_s\right) = \mathbb{E}\left[X_s + (X_t - X_s) \mid \mathscr{F}_s\right] = X_s + \mathbb{E}(X_t - X_s) = X_s \tag{18.1.17}$$

The next martingale is a little more interesting.

Let 
$$Y_t = X_t^2 - t$$
 for  $t \in [0, \infty)$ . Then  $\mathbf{Y} = \{Y_t : t \in [0, \infty)\}$  is a martingale with respect to  $\mathfrak{F}$ .

Let  $s,\,t\in [0,\infty)$  with s < t . Then

$$Y_t = X_t^2 - t = \left[X_s + (X_t - X_s)\right]^2 - t = X_s^2 + 2X_s(X_t - X_s) + (X_t - X_s)^2 - t$$
(18.1.18)

Since  $X_s$  is measurable with respect to  $\mathscr{F}_s$  and  $X_t - X_s$  is independent of  $\mathscr{F}_s$  we have

$$\mathbb{E}\left(Y_t \mid \mathscr{F}_s\right) = X_s^2 + 2X_s \mathbb{E}(X_t - X_s) + \mathbb{E}\left[(X_t - X_s)\right]^2 - t$$
But  $\mathbb{E}(X_t - X_s) = 0$  and  $\mathbb{E}\left[(X_t - X_s)^2\right] = \operatorname{var}(X_t - X_s) = t - s$  so  $\mathbb{E}\left(Y_t \mid \mathscr{F}_s\right) = X_s^2 - s = Y_s$ .
$$(18.1.19)$$

#### Maximums and Hitting Times

As usual, we start with a standard Brownian motion  $X = \{X_t : t \in [0, \infty)\}$ . For  $y \in [0, \infty)$  recall that  $\tau_y = \min\{t \ge 0 : X_t = y\}$  is the first time that the process hits state y. Of course,  $\tau_0 = 0$ . For  $t \in [0, \infty)$ , let  $Y_t = \max\{X_s : 0 \le s \le t\}$ , the maximum value of X on the interval [0, t]. Note that  $Y_t$  is well defined by the continuity of X, and of course  $Y_0 = 0$ . Thus we have two new stochastic processes:  $\{\tau_y : y \in [0, \infty)\}$  and  $\{Y_t : t \in [0, \infty)\}$ . Both have index set  $[0, \infty)$  and (as we will see) state space  $[0, \infty)$ . Moreover, the processes are inverses of each other in a sense:

For  $t, y \in (0, \infty)$ ,  $\tau_y \leq t$  if and only if  $Y_t \geq y$ .

#### Proof

Since standard Brownian motion starts at 0 and is continuous, both events mean that the the process hits state y in the interval [0, t].

Thus, if we can compute the distribution of  $Y_t$  for each  $t \in (0, \infty)$  then we can compute the distribution of  $\tau_y$  for each  $y \in (0, \infty)$ , and conversely.

For y > 0,  $\tau_y$  has the same distribution as  $y^2/Z^2$ , where Z is a standard normal variable. The probability density function  $g_y$  is given by

$$g_y(t) = rac{y}{\sqrt{2\pi t^3}} \exp\left(-rac{y^2}{2t}
ight), \quad t \in (0,\infty)$$
 (18.1.20)

Proof

Let t > 0. From the previous result, note that  $X_t \ge y \implies Y_t \ge y \implies au_y \le t$  . Hence

$$\mathbb{P}(X_t \ge y) = \mathbb{P}(X_t \ge y, \tau_y \le t) = \mathbb{P}(X_t \ge y \mid \tau_y \le t) \mathbb{P}(\tau_y \le t)$$
(18.1.21)

But from the strong Markov property above,  $s \mapsto X(\tau_y + s) - y$  is another standard Brownian motion. Hence  $\mathbb{P}(X_t \ge y \mid \tau_y \le t) = \frac{1}{2}$ . Therefore

$$\mathbb{P}(\tau_y \le t) = 2\mathbb{P}(X_t \ge y) = \frac{2}{\sqrt{2\pi t}} \int_y^\infty e^{-x^2/2t} \, dx = \frac{2}{\sqrt{2\pi}} \int_{y/\sqrt{t}}^\infty e^{-z^2/2} \, dz \tag{18.1.22}$$

The second integral follows from the first by the change of variables  $z = x/\sqrt{t}$ . We can recognize this integral as  $\mathbb{P}(y^2/Z^2 \le t)$  where *Z* has a standard normal distribution. Taking the derivative of the integral with respect to *t* gives the PDF.

The distribution of  $\tau_y$  is the *Lévy distribution* with scale parameter  $y^2$ , and is named for the French mathematician Paul Lévy. The Lévy distribution is studied in more detail in the chapter on special distributions.

Open the hitting time experiment. Vary y and note the shape and location of the probability density function of  $\tau_y$ . For selected values of the parameter, run the simulation in single step mode a few times. Then run the experiment 1000 times and compare the empirical density function to the probability density function.

Open the special distribution simulator and select the Lévy distribution. Vary the parameters and note the shape and location of the probability density function. For selected values of the parameters, run the simulation 1000 times and compare the empirical density function to the probability density function.

Standard Brownian motion is *recurrent*. That is,  $\mathbb{P}(\tau_y < \infty) = 1$  for every  $y \in \mathbb{R}$ .

Proof

Suppose first that y > 0. From the proof of the last theorem,

$$\mathbb{P}(\tau_y < \infty) = \lim_{t \to \infty} \mathbb{P}(\tau_y \le t) = \frac{2}{\sqrt{2\pi}} \int_0^\infty e^{-z^2/2} \, dz = 1 \tag{18.1.23}$$

Note that the integral above is equivalent to the integral of the standard normal PDF over  $\mathbb{R}$ . In particular, the function  $g_y$  given above really is a valid PDF. If y < 0 then by symmetry,  $\tau_y$  has the same distribution as  $\tau_{-y}$ , so  $\mathbb{P}(\tau_y < \infty) = 1$ . Trivially,  $\tau_0 = 0$ .

Thus, for each  $y \in \mathbb{R}$ , X eventually hits y with probability 1. Actually we can say more:

With probability 1,  $\boldsymbol{X}$  visits every point in  $\mathbb{R}$ .

Proof

By continuity, if X reaches y > 0 then X visits every point in [0, y]. By symmetry, a similar statement holds for y < 0. Thus the event that X visits every point in  $\mathbb{R}$  is  $\bigcap_{n=1}^{\infty} (\{\tau_n < \infty\} \cap \{\tau_{-n} < \infty\})$ . The probability of a countable intersection of events with probability 1 still has probability 1.

On the other hand,

Standard Brownian motion is *null recurrent*. That is,  $\mathbb{E}(\tau_y) = \infty$  for every  $y \in \mathbb{R} \setminus \{0\}$ .

Proof

By symmetry, it suffices to consider y > 0. From the result above on the distribution of  $\tau_y$ ,

$$\mathbb{E}(\tau_y) = \int_0^\infty \mathbb{P}(\tau_y > t) \, dt = \frac{2}{\sqrt{2\pi}} \int_0^\infty \int_0^{y/\sqrt{t}} e^{-z^2/2} \, dz \, dt \tag{18.1.24}$$

Changing the order of integration gives

$$\mathbb{E}(\tau_y) = \frac{2}{\sqrt{2\pi}} \int_0^\infty \int_0^{y^2/z^2} e^{-z^2/2} \, dt \, dz = \frac{2y^2}{\sqrt{2\pi}} \int_0^\infty \frac{1}{z^2} e^{-z^2/2} \, dz \tag{18.1.25}$$

Next we get a lower bound on the last integral by integrating over the interval [0, 1] and noting that  $e^{-z^2/2} \ge e^{-1/2}$  on this integral. Thus,

$$\mathbb{E}(\tau_y) \ge \frac{2y^2 e^{-1/2}}{\sqrt{2\pi}} \int_0^1 \frac{1}{z^2} \, dz = \infty \tag{18.1.26}$$

The process  $\{ au_x: x\in [0,\infty)\}$  has stationary, independent increments.

Proof

The proof relies on the temporal and spatial homogeneity of Brownian motion and the strong Markov property. Suppose that  $x, y \in [0, \infty)$  with x < y. By continuity, X must reach x before reaching y. Thus,  $\tau_y = \tau_x + (\tau_y - \tau_x)$ . But  $\tau_y - \tau_x$  is the hitting time to y - x for the process  $t \mapsto X(\tau_x + t) - x$ , and as shown above, this process is also a standard Brownian motion, independent of  $\mathscr{F}(\tau_x)$ . Hence  $\tau_y - \tau_x$  is independent of  $\mathscr{F}(\tau_x)$  and has the same distribution as  $\tau_{y-x}$ .

The family of probability density functions  $\{g_x : x \in (0, \infty)\}$  is closed under convolution. That is,  $g_x * g_y = g_{x+y}$  for  $x, y \in (0, \infty)$ . Proof

This follows immediately from the previous theorem. A direct proof is an interesting exercise.

 $\odot$ 

Now we turn our attention to the maximum process  $\{Y_t : t \in [0, \infty)\}$ , the "inverse" of the hitting process  $\{\tau_y : y \in [0, \infty)\}$ .

For t > 0,  $Y_t$  has the same distribution as  $|X_t|$ , known as the *half-normal distribution* with scale parameter t. The probability density function is

$$h_t(y) = \sqrt{\frac{2}{\pi t}} \exp\left(-\frac{y^2}{2t}\right), \quad y \in [0, \infty)$$
(18.1.27)

Proof

From the inverse relation and the distribution of  $\tau_y$ ,  $\mathbb{P}(Y_t \ge y) = \mathbb{P}(\tau_y \le t) = 2\mathbb{P}(X_t \ge y) = \mathbb{P}(|X_t| \ge y)$  for  $y \ge 0$ . By definition,  $|X_t|$  has the half-normal distribution with parameter t. In particular,

$$\mathbb{P}(Y_t \ge y) = \frac{2}{\sqrt{2\pi t}} \int_y^\infty e^{-x^2/2t} \, dx \tag{18.1.28}$$

Taking the negative derivative of the integral above, with respect to y, gives the PDF.

The half-normal distribution is a special case of the folded normal distribution, which is studied in more detail in the chapter on special distributions.

For  $t \ge 0$  , the mean and variance of  $Y_t$  are

1. 
$$\mathbb{E}(Y_t) = \sqrt{\frac{2t}{\pi}}$$
  
2.  $\operatorname{var}(Y_t) = t\left(1 - \frac{2}{\pi}\right)$ 

Proof

These follow from standard results for the half-normal distribution.

In the standard Brownian motion simulation, select the maximum value. Vary the parameter t and note the shape of the probability density function and the location and size of the mean-standard deviation bar. Run the simulation 1000 times and compare the empirical density and moments to the true probability density function and moments.

Open the special distribution simulator and select the folded-normal distribution. Vary the parameters and note the shape and location of the probability density function and the size and location of the mean-standard deviation bar. For selected values of the parameters, run the simulation 1000 times and compare the empirical density function and moments to the true density function and moments.

#### Zeros and Arcsine Laws

As usual, we start with a standard Brownian motion  $X = \{X_t : t \in [0, \infty)\}$ . Study of the zeros of X lead to a number of probability laws referred to as *arcsine laws*, because as we might guess, the probabilities and distributions involve the arcsine function.

For  $s, t \in [0, \infty)$  with s < t, let E(s, t) be the event that X has a zero in the time interval (s, t). That is,  $\mathbb{E}(s, t) = \{X_u = 0 \text{ for some } u \in (s, t)\}$ . Then

$$\mathbb{P}\left[E(s,t)\right] = 1 - \frac{2}{\pi} \arcsin\left(\sqrt{\frac{s}{t}}\right) \tag{18.1.29}$$

Proof

Conditioning on  $X_s$  and using symmetry gives

$$\mathbb{P}[E(s,t)] = \int_{-\infty}^{\infty} \mathbb{P}[E(s,t) \mid X_s = x] f_s(x) \, dx = 2 \int_{-\infty}^{0} \mathbb{P}[E(s,t) \mid X_s = x] f_s(x) \, dx \tag{18.1.30}$$

But by the homogeneity of X in time and space, note that for x > 0,  $\mathbb{P}[E(s,t) | X_s = -x] = \mathbb{P}(\tau_x < t - s)$ . That is, a process in state -x at time s that hits 0 before time t is the same as a process in state 0 at time 0 reaching state x before time t - s. Hence

$$\mathbb{P}[E(s,t)] = \int_0^\infty \int_0^{t-s} g_x(u) f_s(-x) \, du \, dx \tag{18.1.31}$$

where  $g_x$  is the PDF of  $\tau_x$  given above. Substituting gives

$$\mathbb{P}\left[E(s,t)\right] = \frac{1}{\pi\sqrt{s}} \int_0^{t-s} u^{-3/2} \int_0^\infty x \exp\left[-\frac{1}{2}x^2\left(\frac{u+s}{us}\right)\right] dx \, du = \frac{\sqrt{s}}{\pi} \int_0^{t-s} \frac{1}{(u+s)\sqrt{u}} \, du \tag{18.1.32}$$

Finally substituting  $v = \sqrt{u/s}$  in the last integral give

$$\mathbb{P}[E(s,t)] = \frac{2}{\pi} \int_0^{\sqrt{t/s-1}} \frac{1}{v^2+1} \, dv = \frac{2}{\pi} \arctan\left(\sqrt{\frac{t}{s}-1}\right) = 1 - \frac{2}{\pi} \operatorname{arcsin}\left(\sqrt{\frac{s}{t}}\right) \tag{18.1.33}$$

In paricular,  $\mathbb{P}[E(0,t)] = 1$  for every t > 0, so with probability 1, **X** has a zero in (0,t). Actually, we can say a bit more:

For t > 0, **X** has infinitely many zeros in (0, t) with probability 1.

Proof

The event that X has infinitely many zeros in (0, t) is  $\bigcap_{n=1}^{\infty} E(0, t/n)$ . The intersection of a countable collection of events with probability 1 still has probability 1.

The last result is further evidence of the very strange and irregular behavior of Brownian motion. Note also that  $\mathbb{P}[E(s,t)]$  depends only on the ratio s/t. Thus,  $\mathbb{P}[E(s,t)] = \mathbb{P}[E(1/t, 1/s)]$  and  $\mathbb{P}[E(s,t)] = \mathbb{P}[E(cs,ct)]$  for every c > 0. So, for example the probability of at least one zero in the interval (2,5) is the same as the probability of at least one zero in (1/5, 1/2) the same as the probability of at least one zero in (6, 15), and the same as the probability of at least one zero in (200, 500)

For t > 0, let  $Z_t$  denote the time of the last zero of X before time t. That is,  $Z_t = \max \{s \in [0, t] : X_s = 0\}$ . Then  $Z_t$  has the *arcsine distribution* with parameter t. The distribution function  $H_t$  and the probability density function  $h_t$  are given by

$$H_t(s) = \frac{2}{\pi} \arcsin\left(\sqrt{\frac{s}{t}}\right), \quad 0 \le s \le t$$
(18.1.34)

$$h_t(s) = rac{1}{\pi \sqrt{s(t-s)}}, \quad 0 < s < t$$
 (18.1.35)

Proof

For  $0 \le s < t$ , the event  $Z_t \le s$  is the same as  $[\underline{\text{Vef}[E(s, t)]}]$ , that there are no zeros in the interval (s, t). Hence the formula for  $H_t$  follows from the result above. Taking the derivative of  $H_t$  and simplifying gives the formula for  $h_t$ .

The density function of  $Z_t$  is *u*-shaped and symmetric about the midpoint t/2, so the points with the largest density are those near the endpoints 0 and t, a surprising result at first. The arcsine distribution is studied in more detail in the chapter on special distributions.

The mean and variance of  $Z_t$  are

1. 
$$\mathbb{E}(Z_t) = t/2$$
  
2.  $\mathbb{E}(Z_t) = t^2/8$ 

Proof

These are standard results for the arcsine distribution. That the mean is the midpoint t/2 also follows from symmetry, of course.

In the simulation of standard Brownian motion, select the last zero variable. Vary the parameter t and note the shape of the probability density function and the size and location of the mean-standard deviation bar. For selected values of t run the simulation is single step mode a few times and note the position of the last zero. Finally, run the simulation 1000 times and compare the empirical density function and moments to the true probability density function and moments.

Open the special distribution simulator and select the arcsine distribution. Vary the parameters and note the shape and location of the probability density function and the size and location of the mean-standard deviation bar. For selected values of the parameters, run the simulation 1000 times and compare the empirical density function and moments to the true density function and moments.

Now let  $Z = \{t \in [0, \infty) : X_t = 0\}$  denote the set of zeros of X, so that Z is a random subset of  $[0, \infty)$ . The theorem below gives some of the strange properties of the random set Z, but to understand these, we need to review some definitions. A *nowhere dense* set is a set whose closure has empty interior. A *perfect set* is a set with no isolated points. As usual, we let  $\lambda$  denote Lebesgue measure on  $\mathbb{R}$ .

With probability 1,

1. Z is closed.

2.  $\lambda(Z) = 0$ 

3. Z is nowhere dense.

4. Z is perfect.

Proof

1. Note that *Z* is the inverse image of the closed set  $\{0\}$  under the function  $t \mapsto X_t$ . Since this function is continuous with probability 1, *Z* is closed with probability 1.

2. For each  $t \in (0, \infty)$  note that  $\mathbb{P}(t \in Z) = \mathbb{P}(X_t = 0) = 0$  since  $X_t$  has a continuous distribution. Using Fubini's theorem

$$\mathbb{E}\left[\lambda(Z)\right] = \mathbb{E}\left[\int_0^\infty \mathbf{1}_Z(t) \, d\lambda(t)\right] = \int_0^\infty \mathbb{E}\left[\mathbf{1}_Z(t)\right] \, d\lambda(t) = 0 \tag{18.1.36}$$

and hence  $\mathbb{P}\left[\lambda(Z)=0
ight]=1$  ,

- 3. Since Z is closed and has Lebesgue measure 0, it's interior is empty (all of these statements with probability 1).
- 4. Suppose that  $s \in Z$ . Then by the temporal and spatial homogeneity properties,  $t \mapsto X_{s+t}$  is also a standard Brownian motion. But then by the result above on zeros, with probability 1, X has a zero in the interval (s, s + 1/n) for every  $n \in \mathbb{N}_+$ . Hence s is not an isolated point of Z.

The following theorem gives a deeper property of Z. The Hausdorff dimension of Z is midway between that of a point (dimension 0) and a line (dimension 1).

*Z* has Hausdorff dimension  $\frac{1}{2}$ .

#### The Law of the Iterated Logarithm

As usual, let  $X = \{X_t : t \in [0, \infty)\}$  be standard Brownian motion. By definition, we know that  $X_t$  has the normal distribution with mean 0 and standard deviation  $\sqrt{t}$ , so the function  $x = \sqrt{t}$  gives some idea of how the process grows in time. The precise growth rate is given by the famous *law of the iterated logarithm* 

With probability 1,

$$\limsup_{t \to \infty} \frac{X_t}{\sqrt{2t \ln \ln t}} = 1 \tag{18.1.37}$$

#### **Computational Exercises**

In the following exercises,  $X = \{X_t : t \in [0, \infty)\}$  is a standard Brownian motion process.

Explicitly find the probability density function, covariance matrix, and correlation matrix of  $(X_{0.5}, X_1, X_{2.3})$ .

## 18.2: Brownian Motion with Drift and Scaling

## Basic Theory

#### Definition

We start with the assumptions that govern standard Brownian motion, except that we relax the restrictions on the parameters of the normal distribution.

Suppose that  $\mu \in \mathbb{R}$  and  $\sigma \in (0, \infty)$ . *Brownian motion* with drift parameter  $\mu$  and scale parameter  $\sigma$  is a random process  $X = \{X_t : t \in [0, \infty)\}$  with state space  $\mathbb{R}$  that satisfies the following properties:

- 1.  $X_0 = 0$  (with probability 1).
- 2. *X* has stationary increments. That is, for  $s, t \in [0, \infty)$  with s < t, the distribution of  $X_t X_s$  is the same as the distribution of  $X_{t-s}$ .
- 3. **X** has independent increments. That is, for  $t_1, t_2, \ldots, t_n \in [0, \infty)$  with  $t_1 < t_2 < \cdots < t_n$ , the random variables  $X_{t_1}, X_{t_2} X_{t_1}, \ldots, X_{t_n} X_{t_{n-1}}$  are independent.
- 4.  $X_t$  has the normal distribution with mean  $\mu t$  and variance  $\sigma^2 t$  for  $t \in [0, \infty)$ .
- 5. With probability 1,  $t \mapsto X_t$  is continuous on  $[0, \infty)$ .

Note that we cannot assign the parameters of the normal distribution of  $X_t$  arbitrarily. We know that since X has stationary, independent increments,  $\mathbb{E}(X_t)$  and  $var(X_t)$  must be linear functions of  $t \in [0, \infty)$ .

Open the simulation of Brownian motion with drift and scaling. Run the simulation in single step mode several times for various values of the parameters. Note the behavior of the sample paths. For selected values of the parameters, run the simulation 1000 times and compare the empirical density function and moments to the true density function and moments.

It's easy to construct Brownian motion with drift and scaling from a standard Brownian motion, so we don't have to worry about the existence question.

Relation to standard Brownian motion.

- 1. Suppose that  $\mathbf{Z} = \{Z_t : t \in [0, \infty)\}$  is a standard Brownian motion, and that  $\mu \in \mathbb{R}$  and  $\sigma \in (0, \infty)$ . Let  $X_t = \mu t + \sigma Z_t$  for  $t \in [0, \infty)$ . Then  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  is a Brownian motion with drift parameter  $\mu$  and scale parameter  $\sigma$ .
- 2. Conversely, suppose that  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  is a Brownian motion with drift parameter  $\mu \in \mathbb{R}$  and scale parameter  $\sigma \in (0, \infty)$ . Let  $Z_t = (X_t \mu t) / \sigma$  for  $t \in [0, \infty)$ . Then  $\mathbf{Z} = \{Z_t : t \in [0, \infty)\}$  is a standard Brownian motion.

#### Proof

It's straightforwrd to show that the processes X and Z satisfy the appropriate set of assumptions.

In differential form, part (a) can be written as

$$dX_t = \mu \, dt + \sigma \, dZ_t, \ X_0 = 0 \tag{18.2.1}$$

#### **Finite Dimensional Distributions**

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  is Brownian motion with drift parameter  $\mu \in \mathbb{R}$  and scale parameter  $\sigma \in (0, \infty)$ . It follows from part (d) of the definition that  $X_t$  has probability density function  $f_t$  given by

$$f_t(x) = \frac{1}{\sigma\sqrt{2\pi t}} \exp\left[-\frac{1}{2\sigma^2 t}(x-\mu t)^2\right], \quad x \in \mathbb{R}$$
(18.2.2)

This family of density functions determines the finite dimensional distributions of X.

If  $t_1, t_2, \ldots, t_n \in (0, \infty)$  with  $0 < t_1 < t_2 \cdots < t_n$  then  $(X_{t_1}, X_{t_2}, \ldots, X_{t_n})$  has probability density function  $f_{t_1, t_2, \ldots, t_n}$  given by

$$f_{t_1,t_2,\ldots,t_n}(x_1,x_2,\ldots,x_n) = f_{t_1}(x_1)f_{t_2-t_1}(x_2-x_1)\cdots f_{t_n-t_{n-1}}(x_n-x_{n-1}), \quad (x_1,x_2,\ldots,x_n) \in \mathbb{R}^n \quad (18.2.3)$$

#### Proof

This follows because  $\boldsymbol{X}$  has stationary, independent increments.

 $\boldsymbol{X}$  is a Gaussian process with mean function mean function m and covariance function c given by

1.  $m(t) = \mu t$  for  $t \in [0, \infty)$ 2.  $c(s, t) = \sigma^2 \min\{s, t\}$  for  $s, t \in [0, \infty)$ .

#### Proof

The fact that X is a Gaussian process follows from the construction  $X_t = \mu t + \sigma Z_t$  for  $t \in [0, \infty)$ , where Z is a standard Brownian motion. We know that Z is a Gaussian process. The form of the mean and covariance functions follow because X has stationary, independent increments. Note that  $\mu$  and  $\sigma^2$  are the mean and variance of  $X_1$ .

The correlation function is independent of the parameters, and thus is the same as for standard Brownian motion. This is hardly surprising since correlation is a standardized measure of association.

$$cor(X_s, X_t) \frac{\sigma^2 \min\{s, t\}}{\sigma s \sigma t} = \frac{\min\{s, t\}}{st} = \sqrt{\frac{\min\{s, t\}}{\max\{s, t\}}}, \quad (s, t) \in [0, \infty)^2$$
(18.2.4)

#### Transformations

There are a couple simple transformations that preserve Brownian motion, but perhaps change the drift and scale parameters. Our starting place is a Brownian motion  $\mathbf{X} = \{X_t : t \in [0, \infty)\}$  with drift parameter  $\mu \in \mathbb{R}$  and scale parameter  $\sigma \in (0, \infty)$ . Our first result involves scaling  $\mathbf{X}$  is time and space (and possible reflecting in the spatial origin).

Let  $a \in \mathbb{R} \setminus \{0\}$  and  $b \in (0, \infty)$ . Define  $Y_t = aX_{bt}$  for  $t \ge 0$ . Then  $\mathbf{Y} = \{Y_t : t \ge 0\}$  is also a Brownian motion with drift parameter  $ab\mu$  and scale parameter  $|a| \sqrt{b\sigma}$ .

Proof

Clearly the new process is still a Gaussian process. The mean function is  $\mathbb{E}(Y_t) = a\mathbb{E}(X_{bt}) = ab\mu t$  for  $t \in [0, \infty)$ . The covariance function is  $\operatorname{cov}(Y_s, Y_t) = a^2 \operatorname{cov}(X_{bs}, X_{bt}) = a^2 \sigma^2 \min\{bs, bt\} = a^2 b\sigma^2 \min\{s, t\}$  for  $(s, t) \in [0, \infty)^2$ . Finally, since X is continuous, so is Y.

Suppose that a > 0 in the previous theorem, so that we are scaling temporally and spatially. In order to preserve the original drift parameter  $\mu$  we must have ab = 1 (if  $\mu \neq 0$ ). In order to preserve the original scale parameter  $\sigma$ , we must have  $a\sqrt{b} = 1$ . We can't have both unless  $\mu = 0$ , which leads to a slight generalization of one of our results for standard Brownian motion:

Suppose that X is a Brownian motion with drift parameter  $\mu = 0$  and scale parameter  $\sigma > 0$ . Suppose also that c > 0 and let  $Y_t = \frac{1}{c} X_{c^2 t}$  for  $t \ge 0$ . Then  $Y = \{Y_t : t \in [0, \infty)\}$  is also a Brownian motion with drift parameter 0 and scale parameter  $\sigma$ .

Our next result is related to the Markov property, which we explore in more detail below. We return to the general case where  $X = \{X_t : t \in [0, \infty)\}$  is a Brownian motion with drift parameter  $\mu \in \mathbb{R}$  and scale parameter  $\sigma \in (0, \infty)$ . If we "restart" Brownian motion at a fixed time s, and shift the origin to  $X_s$ , then we have another Brownian motion with the same parameters.

Fix  $s \in [0, \infty)$  and define  $Y_t = X_{s+t} - X_s$  for  $t \ge 0$ . Then  $\mathbf{Y} = \{Y_t : t \in [0, \infty)\}$  is also a Brownian motion with the same drift and scale parameters.

Proof

Clearly  $\boldsymbol{Y}$  is also a Gaussian process. Moreover,  $\mathbb{E}(Y_t) = \mathbb{E}(X_{s+t}) - \mathbb{E}(X_s) = \mu(s+t) - \mu s = \mu t$  for  $t \in [0, \infty)$ . Also, if  $r, t \in [0, \infty)$  with  $r \leq t$  then

$$cov(Y_r, Y_t) = cov(X_{s+r} - X_s, X_{s+t} - X_s)$$
(18.2.5)

$$= \operatorname{cov}(X_{s+r}, X_{s+t}) - \operatorname{cov}(X_{s+r}, X_s) - \operatorname{cov}(X_s, X_{s+t}) + \operatorname{cov}(X_s, X_s)$$
(18.2.6)

$$=\sigma^{2}(s+r) - \sigma^{2}s - \sigma^{2}s + \sigma^{2}s = \sigma^{2}r$$
(18.2.7)

Finally,  $\boldsymbol{Y}$  is continuous by the continuity of  $\boldsymbol{X}$ .

#### The Markov Property and Stopping Times

As usual, we start with a Brownian motion  $X = \{X_t : t \in [0, \infty)\}$  with drift parameter  $\mu$  and scale parameter  $\sigma$ . Recall again that a Markov process has the property that the future is independent of the past, given the present state. Because of the stationary, independent increments property, Brownian motion has the property. As a minor note, to view X as a Markov process, we sometimes need to relax Assumption 1 and let  $X_0$  have an arbitrary value in  $\mathbb{R}$ . Let  $\mathscr{F}_t = \sigma\{X_s : 0 \le s \le t\}$ , the sigma-algebra generated by the process up to time  $t \in [0, \infty)$ . The family of  $\sigma$ -algebras  $\mathfrak{F} = \{\mathscr{F}_t : t \in [0, \infty)\}$  is known as a filtration.

Brownian motion is a time-homogeneous Markov process with transition probability density p given by

$$p_t(x,y) = f_t(y-x) = rac{1}{\sigma\sqrt{2\pi t}} \mathrm{exp}igg[ -rac{1}{2\sigma^2 t} (y-x-\mu t)^2 igg], \quad t\in(0,\infty); \; x,\,y\in\mathbb{R}$$
 (18.2.8)

Proof

Fix  $s \in [0, \infty)$ . The theorem follows from the fact that the process  $\{X_{s+t} - X_s : t \in [0, \infty)\}$  is another standard Brownian motion, as noted above, and is independent of  $\mathscr{P}_s$ .

The transition density *p* satisfies the following *diffusion equations*. The first is known as the *forward equation* and the second as the *backward equation*.

$$rac{\partial}{\partial t}p_t(x,y) = -\mu rac{\partial}{\partial y}p_t(x,y) + rac{1}{2}\sigma^2 rac{\partial^2}{\partial y^2}p_t(x,y)$$
(18.2.9)

$$\frac{\partial}{\partial t}p_t(x,y) = \mu \frac{\partial}{\partial x}p_t(x,y) + \frac{1}{2}\sigma^2 \frac{\partial^2}{\partial x^2}p_t(x,y)$$
 (18.2.10)

Proof

These results follows from standard calculus.

The diffusion equations are so named, because the spatial derivative in the first equation is with respect to y, the state *forward* at time t, while the spatial derivative in the second equation is with respect to x, the state *backward* at time 0.

Recall again that a random time  $\tau$  taking values in  $[0, \infty]$  is a *stopping time* with respect to the process X if  $\{\tau \leq t\} \in \mathscr{F}_t$  for every  $t \in [0, \infty)$ . The  $\sigma$ -algebra associated with  $\tau$  is

$$\mathscr{F}_{\tau} = \{ B \in \mathscr{F} : B \cap \{ \tau \le t \} \in \mathscr{F}_t \text{ for all } t \ge 0 \}$$

$$(18.2.11)$$

See the section on Filtrations and Stopping Times for more information on filtrations, stopping times, and the  $\sigma$ -algebra associated with a stopping time. Brownian motion X is also a strong Markov process.

Suppose that  $\tau$  is a stopping time and define  $Y_t = X_{\tau+t} - X_{\tau}$  for  $t \in [0, \infty)$ . Then  $\mathbf{Y} = \{Y_t : t \in [0, \infty)\}$  is a Brownian motion with the same drift and scale parameters, and is independent of  $\mathscr{F}_{\tau}$ .

### 18.3: The Brownian Bridge

#### **Basic Theory**

#### Definition and Constructions

In the most common formulation, the *Brownian bridge process* is obtained by taking a standard Brownian motion process X, restricted to the interval [0, 1], and conditioning on the event that  $X_1 = 0$ . Since  $X_0 = 0$  also, the process is "tied down" at both ends, and so the process in between forms a "bridge" (albeit a very jagged one). The Brownian bridge turns out to be an interesting stochastic process with surprising applications, including a very important application to statistics. In terms of a definition, however, we will give a list of characterizing properties as we did for standard Brownian motion and for Brownian motion with drift and scaling.

A Brownian bridge is a stochastic process  $X = \{X_t : t \in [0, 1]\}$  with state space  $\mathbb{R}$  that satisfies the following properties:

1.  $X_0 = 0$  and  $X_1 = 0$  (each with probability 1). 2. X is a Gaussian process. 3.  $\mathbb{E}(X_t) = 0$  for  $t \in [0, 1]$ . 4.  $\operatorname{cov}(X_s, X_t) = \min\{s, t\} - st$  for  $s, t \in [0, 1]$ . 5. With probability 1,  $t \mapsto X_t$  is continuous on [0, 1].

So, in short, a Brownian bridge X is a continuous Gaussian process with  $X_0 = X_1 = 0$ , and with mean and covariance functions given in (c) and (d), respectively. Naturally, the first question is whether there exists such a process. The answer is yes, of course, otherwise why would we be here? But in fact, we will see several ways of constructing a Brownian bridge from a standard Brownian motion. To help with the proofs, recall that a standard Brownian motion process  $Z = \{Z_t : t \in [0, \infty)\}$  is a continuous Gaussian process with  $Z_0 = 0$ ,  $\mathbb{E}(Z_t) = 0$  for  $t \in [0, \infty)$  and  $\operatorname{cov}(Z_s, Z_t) = \min\{s, t\}$  for  $s, t \in [0, \infty)$ . Here is our first construction:

Suppose that  $\mathbf{Z} = \{Z_t : t \in [0, \infty)\}$  is a standard Brownian motion, and let  $X_t = Z_t - tZ_1$  for  $t \in [0, 1]$ . Then  $\mathbf{X} = \{X_t : t \in [0, 1]\}$  is a Brownian bridge.

Proof

1. Note that  $X_0=Z_0=0~~{
m and}~ X_1=Z_1-Z_1=0~~{
m .}$ 

- 2. Linear combinations of the variables in *X* reduce to linear combinations of the variables in *Z* and hence have normal distributions. Thus *X* is a Gaussian process.
- 3.  $E(X_t) = \mathbb{E}(Z_t) t\mathbb{E}(Z_1) = 0$  for  $t \in [0, 1]$

 $4. \operatorname{cov}(X_s, X_t) = \operatorname{cov}(Z_s - sZ_1, Z_t - tZ_1) = \operatorname{cov}(Z_s, Z_t) - t \operatorname{cov}(Z_s, Z_1) - s \operatorname{cov}(Z_1, Z_t) + st \operatorname{cov}(Z_1, Z_1) = \min\{s, t\} - st - st + st \quad \text{for } s, t \in [0, 1].$ 

5.  $t \mapsto X_t$  is continuous on [0, 1] since  $t \mapsto Z_t$  is continuous on [0, 1].

Let's see the Brownian bridge in action.

Run the simulation of the Brownian bridge process in single step mode a few times.

For the Brownian bridge X, note in particular that  $X_t$  is normally distributed with mean 0 and variance t(1-t) for  $t \in [0, 1]$ . Thus, the variance increases and then decreases on [0, 1] reaching a maximum of 1/4 at t = 1/2. Of course, the variance is 0 at t = 0 and t = 1, since  $X_0 = X_1 = 0$  deterministically.

Open the simulation of the Brownian bridge process. Vary t and note the change in the probability density function and moments. For various values of t, run the simulation 1000 times and compare the empirical density function and moments to the true density function and moments.

Conversely to the construction above, we can build a standard Brownian motion on the time interval [0, 1] from a Brownian bridge.

Suppose that  $X = \{X_t : t \in [0,1]\}$  is a Brownian bridge, and suppose that Z is a random variable with a standard normal distribution, independent of X. Let  $Z_t = X_t + tZ$  for  $t \in [0,1]$ . Then  $Z = \{Z_t : t \in [0,1]\}$  is a standard Brownian motion on [0,1].

Proof

1. Note that  $Z_0 = X_0 = 0$  .

2. Linear combinations of the variables in *Z* reduce to linear combinations of the variables in *X* and hence have normal distributions. Thus *Z* is a Gaussian process.

3.  $\mathbb{E}(Z_t) = \mathbb{E}(X_t) + t\mathbb{E}(Z) = 0 \quad ext{for } t \in [0,1].$ 

4.

$$\begin{array}{l} \cos(Z_s,Z_t) = \cos(X_s + sZ,X_t + tZ) = \cos(X_s,X_t) + t \cos(X_s,Z) + s \cos(X_t,Z) + st \sin\{s,t\} - st + 0 + 0 + st = \min\{s,t\} \\ \text{for } s, t \in [0,1]. \end{array}$$

5. 
$$t \mapsto Z_t$$
 is continuous on  $[0, 1]$  since  $t \mapsto X_t$  is continuous on  $[0, 1]$ .

Here's another way to construct a Brownian bridge from a standard Brownian motion.

Suppose that  $\mathbf{Z} = \{Z_t : t \in [0,\infty)\}$  is a standard Brownian motion. Define  $X_1 = 0$  and

$$X_t = (1-t)Z\left(\frac{t}{1-t}\right), \quad t \in [0,1)$$
(18.3.1)

Then  $oldsymbol{X} = \{X_t: t \in [0,1]\}$  is a Brownian bridge.

Proof

- 1. Note that  $X_0 = Z_0 = 0$  and by definition,  $X_1 = 0$ .
- 2. Linear combinations of variables in *X* reduce to linear combinations of variables in *Z* and hence have normal distributions. Thus *X* is a Gaussian process.
- 3. For  $t\in [0,1]$ ,

$$\mathbb{E}(X_t) = (1-t)\mathbb{E}\left[Z\left(\frac{t}{1-t}\right)\right] = 0$$
(18.3.2)

4. If  $s, \, t \in [0,1)$  with s < t then s / (1-s) < t / (1-t) so

$$\operatorname{cov}(X_s, X_t) = \operatorname{cov}\left[ (1-s)Z\left(\frac{s}{1-s}\right), (1-t)Z\left(\frac{t}{1-t}\right) \right] = (1-s)(1-t)\frac{s}{1-s} = s(1-t)$$
(18.3.3)

5. Finally,  $t \mapsto X_t$  is continuous with probability 1 on [0, 1), and with probability 1,  $X_t = (1 - t)Z[t/(1 - t)] \rightarrow 0$  as  $t \uparrow 1$ .

Conversely, we can construct a standard Brownian motion from a Brownian bridge.

Suppose that  $X = \{X_t : t \in [0, 1]\}$  is a Brownian bridge. Define

$$Z_t = (1+t)X\left(\frac{t}{1+t}\right), \quad t \in [0,\infty)$$
(18.3.4)

Then  $oldsymbol{Z} = \{Z_t : t \in [0,\infty)\}$  is a standard Brownian motion process.

Proof

- 1. Note that  $Z_0 = X_0 = 0$
- 2. Linear combinations of the variables in *Z* reduce to linear combinations of the variables in *X*, and hence have normal distributions. Thus *Z* is a Gaussian process.

3. For  $t \in [0, \infty)$ ,

$$\mathbb{E}(Z_t) = (1+t)\mathbb{E}\left[X\left(\frac{t}{1+t}\right)\right] = 0$$
(18.3.5)

4. If  $s, t \in [0,1]$  with s < t Then s/(1+s) < t/(1+t) so

$$\operatorname{cov}(Z_s, Z_t) = \operatorname{cov}\left[ (1+s)X\left(\frac{s}{1+s}\right), (1+t)X\left(\frac{t}{1+t}\right) \right] = (1+s)(1+t)\left[\frac{s}{1+s} - \frac{s}{1+s}\frac{t}{1+t}\right] = s$$
(18.3.6)

5. Since  $t \mapsto X_t$  is continuous,  $t \mapsto Z_t$  is continuous

We return to the comments at the beginning of this section, on conditioning a standard Brownian motion to be 0 at time 1. Unlike the previous two constructions, note that we are not transforming the random variables, rather we are changing the underlying *probability measure*.

Suppose that  $X = \{X_t : t \in [0, \infty)\}$  is a standard Brownian motion. Then conditioned on  $X_1 = 0$ , the process  $\{X_t : t \in [0, 1]\}$  is a Brownian bridge process.

Proof

Part of the argument is based on properties of the multivariate normal distribution. The conditioned process is still continuous and is still a Gaussian process. In particular, suppose that  $s, t \in [0, 1]$  with s < t. Then  $(X_t, X_1)$  has a joint normal distribution with parameters specified by the mean and covariance functions of X. By standard computations, the conditional distribution of  $X_t$  given  $X_1 = 0$  is normal with mean 0 and variance t(1-t). Similarly, the joint distribution of  $(X_s, X_t, X_1)$  is normal with parameters specified by the mean and covariance functions of X. Again, by standard computations, the conditional distribution of  $(X_s, X_t)$  given  $X_1 = 0$  is bivariate normal with 0 means and with  $cov(X_s, X_t | X_1 = 0) = s(1-t)$ .

Finally, the Brownian bridge can be defined in terms a stochastic integral

Suppose that  $\mathbf{Z} = \{Z_t : t \in [0, \infty)\}$  is standard Brownian motions. Define  $X_1 = 1$  and

$$X_t = (1-t) \int_0^t \frac{1}{1-s} \, dZ_s, \quad t \in [0,1) \tag{18.3.7}$$

Then  $oldsymbol{X} = \{X_t: t \in [0,1]\}$  is a Brownian bridge process. Proof

- 1. Note that  $X_0 = 0$  and by definition,  $X_1 = 0$ .
- 2. Since the integrand in the stochastic integral is deterministic,  $\boldsymbol{X}$  is a Gaussian process.
- 3. *X* is continuous on [0, 1) with probability 1, as a basic property of stochastic integrals. Moreover,  $X_t \rightarrow 0$  as  $t \uparrow 1$  as a consequence of the martingale inequality.
- 4.  $\mathbb{E}(X_t) = 0$  since the stochastic integral has mean 0.
- 5. Suppose that  $s, t \in [0, 1]$  with  $s \leq t$  . Then

$$\operatorname{cov}(X_s, X_t) = \operatorname{cov}\left[ (1-s) \int_0^s \frac{1}{1-u} \, dZ_u, (1-t) \left( \int_0^s \frac{1}{1-u} \, dZ_u + \int_s^t \frac{1}{1-u} \, dZ_u \right) \right]$$
(18.3.8)

But  $\int_0^s \frac{1}{1-u} \, dZ_u$  and  $\int_s^t \frac{1}{1-u} \, dZ_u$  are independent,

$$\operatorname{cov}(X_s, X_t) = (1-s)(1-t)\operatorname{var}\left(\int_0^s \frac{1}{1-u} \, dZ_u\right)$$
(18.3.9)

But then by the Ito isometry,

$$\operatorname{cov}(X_s, X_t) = (1-s)(1-t) \int_0^s \frac{1}{(1-u)^2} \, du = (1-s)(1-t) \left(\frac{1}{1-s} - 1\right) = (1-t)s \tag{18.3.10}$$

In differential form, the process above can be written as

$$dX_t = \frac{X_t}{1-t} dt + dZ_t, \ X_0 = 0 \tag{18.3.11}$$

#### The General Brownian Bridge

The processes constructed above (in several ways!) is the *standard* Brownian bridge. it's a simple matter to generalize the process so that it starts at a and ends at b, for arbitrary  $a, b \in \mathbb{R}$ .

Suppose that  $Z = \{Z_t : t \in [0,1]\}$  is a standard Brownian bridge process. Let  $a, b \in \mathbb{R}$  and define  $X_t = (1-t)a + tb + Z_t$  for  $t \in [0,1]$ . Then  $X = \{X_t : t \in [0,1]\}$  is a Brownian bridge process from a to b.

Of course, any of the constructions above for standard Brownian bridge can be modified to produce a general Brownian bridge. Here are the characterizing properties.

The Brownian bridge process  $X = \{X_t : t \in [0, 1]\}$  from *a* to *b* is characterized by the following properties:

1.  $X_0 = a$  and  $X_1 = b$  (each with probability 1). 2. X is a Gaussian process. 3.  $\mathbb{E}(X_t) = (1-t)a + tb$  for  $t \in [0, 1]$ . 4.  $\operatorname{cov}(X_s, X_t) = \min\{s, t\} - st$  for  $s, t \in [0, 1]$ . 5. With probability 1,  $t \mapsto X_t$  is continuous on [0, 1].

#### Applications

#### The Empirical Distribution Function

We start with a problem that is one of the most basic in statistics. Suppose that T is a real-valued random variable with an unknown distribution. Let F denote the distribution function of T, so that  $F(t) = \mathbb{P}(T \le t)$  for  $t \in \mathbb{R}$ . Our goal is to construct an estimator of F, so naturally our first step is to *sample* from the distribution of T. This generates a sequence  $T = (T_1, T_2, ...)$  of independent variables, each with the distribution of T (and so with distribution function F). Think of T as a sequence of independent *copies* of T. For  $n \in \mathbb{N}_+$  and  $t \in \mathbb{R}$ , the natural estimator of F(t) based on the first n sample values is

$$F_n(t) = \frac{1}{n} \sum_{i=1}^n \mathbf{1}(T_i \le t)$$
(18.3.12)

which is simply the proportion of the first n sample values that fall in the interval  $(-\infty, t]$ . Appropriately enough,  $F_n$  is known as the *empirical distribution function* corresponding to the sample of size n. Note that  $(\mathbf{1}(T_1 \leq t), \mathbf{1}(T_2 \leq t), \ldots)$  is a sequence of independent, identically distributed indicator variables (and hence is a sequence of Bernoulli trials), and corresponds to sampling from the distribution of  $\mathbf{1}(T \leq t)$ . The estimator  $F_n(t)$  is simply the sample mean of the first n of these variables. The numerator, the number of the original sample variables with values in  $(-\infty, t]$ , has the binomial distribution with parameters n and F(t). Like all sample means from independent, identically distributed samples,  $F_n(t)$  satisfies some basic and important properties. A summary is given below, but to make sense of some of these facts, you need to recall the mean and variance of the indicator variable that we are sampling from:  $\mathbb{E} [\mathbf{1}(T \leq t)] = F(t)$ ,  $\operatorname{var} [\mathbf{1}(T \leq t)] = F(t) [\mathbf{1} - F(t)]$ 

For fixed  $t \in \mathbb{R}$  ,

- 1.  $\mathbb{E}[F_n(t)] = F(t)$  so  $F_n(t)$  is an unbiased estimator of F(t)
- 2. var  $[F_n(t)] = F(t) \left[1 F(t)\right] / n$  so  $F_n(t)$  is a consistent estimator of F(t)

3.  $F_n(t) \to F(t)$  as  $n \to \infty$  with probability 1, the strong law of large numbers.

4.  $\sqrt{n} [F_n(t) - F(t)]$  has mean 0 and variance F(t) [1 - F(t)] and converges to the normal distribution with these parameters as  $n \to \infty$ , the central limit theorem.

The theorem above gives us a great deal of information about  $F_n(t)$  for *fixed* t, but now we want to let t vary and consider the expression in (d), namely  $t \mapsto \sqrt{n} [F_n(t) - F(t)]$ , as a random process for each  $n \in \mathbb{N}_+$ . The key is to consider a very special distribution first.

Suppose that *T* has the standard uniform distribution, that is, the continuous uniform distribution on the interval [0, 1]. In this case the distribution function is simply F(t) = t for  $t \in [0, 1]$ , so we have the sequence of stochastic processes  $\mathbf{X}_n = \{X_n(t) : t \in [0, 1]\}$  for  $n \in \mathbb{N}_+$ , where

$$X_n(t) = \sqrt{n} \left[ F_n(t) - t \right]$$
(18.3.13)

Of course, the previous results apply, so the process  $X_n$  has mean function 0, variance function  $t \mapsto t(1-t)$ , and for fixed  $t \in [0, 1]$ , the distribution  $X_n(t)$  converges to the corresponding normal distribution as  $n \to \infty$ . Here is the new bit of information, the covariance function of  $X_n$  is the same as that of the Brownian bridge!

 $\mathrm{cov}\,[X_n(s),X_n(t)]=\min\{s,t\}-st \;\; ext{for}\;s,\,t\in[0,1].$ 

Proof

Suppose that  $s \leq t$ . From basic properties of covariance,

$$\cos\left[X_n(s), X_n(t)\right] = n \cos\left[F_n(s), F_n(t)\right] = \frac{1}{n} \cos\left(\sum_{i=1}^n \mathbf{1}(T_i \le s), \sum_{j=1}^n \mathbf{1}(T_j \le t)\right) = \frac{1}{n} \sum_{i=1}^n \sum_{j=1}^n \cos\left[\mathbf{1}(T_i \le s)\mathbf{1}(T_j \le t)\right] \quad (18.3.14)$$

But if  $i \neq j$ , the variables  $\mathbf{1}(T_i \leq s)$  and  $\mathbf{1}(T_j \leq t)$  are independent, and hence have covariance 0. On the other hand,

$$\cos\left[\mathbf{1}(T_i \le s), \mathbf{1}(T_i \le t)\right] = \mathbb{P}(T_i \le s, T_i \le t) - \mathbb{P}(T_i \le s)\mathbb{P}(T_i \le t) = \mathbb{P}(T_i \le s) - \mathbb{P}(T_i \le s)\mathbb{P}(T_i \le t) = s - st$$
(18.3.15)

hence

$$\cos\left[X_n(s), X_n(t)\right] = \frac{1}{n} \sum_{i=1}^n \cos\left[\mathbf{1}(T_i \le s), \mathbf{1}(T_i \le t)\right] = s - st$$
(18.3.16)

# 18.4: Geometric Brownian Motion

## Basic Theory

Geometric Brownian motion, and other stochastic processes constructed from it, are often used to model population growth, financial processes (such as the price of a stock over time), subject to random "noise".

#### Definition

Suppose that  $\mathbf{Z} = \{Z_t : t \in [0, \infty)\}$  is standard Brownian motion and that  $\mu \in \mathbb{R}$  and  $\sigma \in (0, \infty)$ . Let

$$X_t = \exp\left[\left(\mu - \frac{\sigma^2}{2}\right)t + \sigma Z_t\right], \quad t \in [0, \infty)$$
(18.4.1)

The stochastic process  $X = \{X_t : t \in [0, \infty)\}$  is geometric Brownian motion with drift parameter  $\mu$  and volatility parameter  $\sigma$ .

Note that the stochastic process

$$\left\{ \left( \mu - \frac{\sigma^2}{2} \right) t + \sigma Z_t : t \in [0, \infty) \right\}$$
(18.4.2)

is Brownian motion with drift parameter  $\mu - \sigma^2/2$  and scale parameter  $\sigma$ , so geometric Brownian motion is simply the exponential of this process. In particular, the process is always positive, one of the reasons that geometric Brownian motion is used to model financial and other processes that cannot be negative. Note also that  $X_0 = 1$ , so the process starts at 1, but we can easily change this. For  $x_0 \in (0, \infty)$ , the process  $\{x_0 X_t : t \in [0, \infty)\}$  is geometric Brownian motion *starting at*  $x_0$ . You may well wonder about the particular combination of parameters  $\mu - \sigma^2/2$  in the definition. The short answer to the question is given in the following theorem:

Geometric Brownian motion  $X = \{X_t : t \in [0, \infty)\}$  satisfies the stochastic differential equation

$$dX_t = \mu X_t \, dt + \sigma X_t \, dZ_t \tag{18.4.3}$$

Note that the deterministic part of this equation is the standard differential equation for exponential growth or decay, with rate parameter  $\mu$ .

Run the simulation of geometric Brownian motion several times in single step mode for various values of the parameters. Note the behavior of the process.

#### Distributions

For  $t \in (0, \infty)$ ,  $X_t$  has the lognormal distribution with parameters  $\left(\mu - \frac{\sigma^2}{2}\right)t$  and  $\sigma\sqrt{t}$ . The probability density function  $f_t$  is given by

$$f_t(x) = \frac{1}{\sqrt{2\pi t}\sigma x} \exp\left(-\frac{\left[\ln(x) - \left(\mu - \sigma^2/2\right)t\right]^2}{2\sigma^2 t}\right), \quad x \in (0,\infty)$$
(18.4.4)

1. *f* increases and then decreases with mode at  $x = \exp\left[\left(\mu - \frac{3}{2}\sigma^2\right)t\right]$ 

2. *f* is concave upward, then downward, then upward again with inflection points at  $x = \exp\left[(\mu - \sigma^2)t \pm \frac{1}{2}\sigma\sqrt{\sigma^2 t^2 + 4t}\right]$ 

Proof

Since the variable  $U_t = (\mu - \sigma^2/2)t + \sigma Z_t$  has the normal distribution with mean  $(\mu - \sigma^2/2)t$  and standard deviation  $\sigma\sqrt{t}$ , it follows that  $X_t = \exp(U_t)$  has the lognormal distribution with these parameters. These result for the PDF then follow directly from the corresponding results for the lognormal PDF.

In particular, geometric Brownian motion is not a Gaussian process.

Open the simulation of geometric Brownian motion. Vary the parameters and note the shape of the probability density function of  $X_t$ . For various values of the parameters, run the simulation 1000 times and compare the empirical density function to the true probability density function.

For  $t \in (0, \infty)$ , the distribution function  $F_t$  of  $X_t$  is given by

$$F_t(x) = \Phi\left[rac{\ln(x) - (\mu - \sigma^2/2)t}{\sigma\sqrt{t}}
ight], \quad x \in (0,\infty)$$
 $(18.4.5)$ 

where  $\Phi$  is the standard normal distribution function.

Proof

Again, this follows directly from the CDF of the lognormal distribution.

For  $t \in (0, \infty)$ , the quantile function  $F_t^{-1}$  of  $X_t$  is given by

$$F_t^{-1}(p) = \exp\left[(\mu - \sigma^2/2)t + \sigma\sqrt{t}\Phi^{-1}(p)
ight], \quad p \in (0,1)$$
(18.4.6)

where  $\Phi^{-1}$  is the standard normal quantile function.

Proof

This follows directly from the lognormal quantile function.

#### Moments

For  $n \in \mathbb{N}$  and  $t \in [0,\infty)$ ,

$$\mathbb{E}\left(X_{t}^{n}\right) = \exp\left\{\left[n\mu + \frac{\sigma^{2}}{2}(n^{2} - n)\right]t\right\}$$
(18.4.7)

Proof

This follows from the formula for the moments of the lognormal distribution.

In terms of the order of the moment n, the dominant term inside the exponential is  $\sigma^2 n^2/2$ . If  $n > 1 - 2\mu/\sigma^2$  then  $n\mu + \frac{\sigma^2}{2}(n^2 - n) > 0$  so  $\mathbb{E}(X_t^n) \to \infty$  as  $t \to \infty$ . The mean and variance follow easily from the general moment result.

 $egin{aligned} & ext{For} \ t \in [0,\infty), \ & 1. \ \mathbb{E}(X_t) = e^{\mu t} \ & 2. \ ext{var}(X_t) = e^{2\mu t} \left( e^{\sigma^2 t} - 1 
ight) \end{aligned}$ 

In particular, note that the mean function  $m(t) = \mathbb{E}(X_t) = e^{\mu t}$  for  $t \in [0, \infty)$  satisfies the deterministic part of the stochastic differential equation above. If  $\mu > 0$  then  $m(t) \to \infty$  as  $t \to \infty$ . If  $\mu = 0$  then m(t) = 1 for all  $t \in [0, \infty)$ . If  $\mu < 0$  then  $m(t) \to 0$  as  $t \to \infty$ .

Open the simulation of geometric Brownian motion. The graph of the mean function m is shown as a blue curve in the main graph box. For various values of the parameters, run the simulation 1000 times and note the behavior of the random process in relation to the mean function.

Open the simulation of geometric Brownian motion. Vary the parameters and note the size and location of the mean $\pm$ standard deviation bar for  $X_t$ . For various values of the parameter, run the simulation 1000 times and compare the empirical mean and standard deviation to the true mean and standard deviation.

## **Properties**

The parameter  $\mu - \sigma^2/2$  determines the asymptotic behavior of geometric Brownian motion.

Asymptotic behavior:

1. If  $\mu > \sigma^2/2$  then  $X_t \to \infty$  as  $t \to \infty$  with probability 1. 2. If  $\mu < \sigma^2/2$  then  $X_t \to 0$  as  $t \to \infty$  with probability 1. 3. If  $\mu = \sigma^2/2$  then  $X_t$  has no limit as  $t \to \infty$  with probability 1.

## Proof

These results follow from the law of the iterative logarithm. Asymptotically, the term  $(\mu - \sigma^2/2) t$  dominates the term  $\sigma Z_t$  as  $t \to \infty$ .

It's interesting to compare this result with the asymptotic behavior of the mean function, given above, which depends only on the parameter  $\mu$ . When the drift parameter is 0, geometric Brownian motion is a martingale.

If  $\mu = 0$ , geometric Brownian motion X is a martingale with respect to the underlying Brownian motion Z.

Proof from stochastic integrals

This is the simplest proof. When  $\mu = 0$ ,  $\boldsymbol{X}$  satisfies the stochastic differential equation  $dX_t = \sigma X_t dZ_t$  and therefore

$$X_t = 1 + \sigma \int_0^t X_s \, dZ_s, \quad t \ge 0$$
 (18.4.8)

The process associated with a stochastic integral is always a martingale, assuming the usual assumptions on the integrand process (which are satisfied here).

#### Direct proof

Let  $\mathscr{F}_t = \sigma\{Z_s : 0 \le s \le t\}$  for  $t \in [0, \infty)$ , so that  $\mathfrak{F} = \{\mathscr{F}_t : t \in [0, \infty)\}$  is the natural filtration associated with  $\mathbb{Z}$ . Let  $s, t \in [0, \infty)$  with  $s \le t$ . We use our usual trick of writing  $Z_t = Z_s + (Z_t - Z_s)$ , to take advantage of the stationary and independent increments properties of Brownian motion. Thus,

$$X_t = \exp\left[-\frac{\sigma^2}{2}t + \sigma Z_s + \sigma(Z_t - Z_s)\right]$$
(18.4.9)

Since  $Z_s$  is measurable with respect to  $\mathscr{F}_s$  and  $Z_t - Z_s$  is independent of  $\mathscr{F}_s$  we have

$$\mathbb{E}\left(X_t \mid \mathscr{F}_s\right) = \exp\left(-\frac{\sigma^2}{2}t + \sigma Z_s\right) \mathbb{E}\left\{\exp[\sigma(Z_t - Z_s)]\right\}$$
(18.4.10)

But  $Z_t - Z_s$  has the normal distribution with mean 0 and variance t - s, so from the formula for the moment generating function of the normal distribution, we have

$$\mathbb{E}\left\{\exp[\sigma(Z_t - Z_s)]\right\} = \exp\left[\frac{\sigma^2}{2}(t - s)\right]$$
(18.4.11)

Substituting gives

$$\mathbb{E}\left(X_t \mid \mathscr{F}_s\right) = \exp\left(-\frac{\sigma^2}{2}s + \sigma Z_s\right) = X_s \tag{18.4.12}$$
